HOW TO USE THIS BOOK xxvii
INTRODUCTION xxix
VOLUME 1 (A-M): 1

A

Abbey, Edward
Absorption
Acclimation
Accounting for nature
Accuracy
Acetone
Acid and base
Acid deposition
Acid mine drainage
Acid rain
Acidification
Activated sludge
Acute effects
Adams, Ansel
Adaptation
Adaptive management
Adirondack Mountains
Adsorption
Aeration
Aerobic
Aerobic sludge digestion
Aerobic/anaerobic systems
Aerosol
Aflatoxin
African Wildlife Foundation
Africanized bees
Agency for Toxic Substances and Disease Registry
Agent Orange
Agglomeration
Agricultural chemicals
Agricultural environmental management
Agricultural pollution
Agricultural Research Service
Agricultural revolution
Agricultural Stabilization and Conservation Service
Agroecology
Agroforestry
AIDS
Air and Waste Management Association
Air pollution
Air pollution control
Air pollution index
Air quality
Air quality control region
Air quality criteria
Airshed
Alar
Alaska Highway
Alaska National Interest Lands Conservation Act (1980)
Albedo
Algal bloom
Algicide
Allelopathy
Allergen
Alligator, American
Alpha particle
Alternative energy sources
Aluminum
Amazon basin
Ambient air
Amenity value
American box turtle
American Cetacean Society
American Committee for International Conservation
American Farmland Trust
American Forests
American Indian Environmental Office
American Oceans Campaign
American Wildlands
Ames test
Amoco Cadiz
Amory, Cleveland

Anaerobic
Anaerobic digestion
Anemia
Animal cancer tests
Animal Legal Defense Fund
Animal rights
Animal waste
Animal Welfare Institute
Antarctic Treaty (1961)
Antarctica
Antarctica Project
Anthrax
Anthropogenic
Antibiotic resistance
Aquaculture
Aquarium trade
Aquatic chemistry
Aquatic microbiology
Aquatic toxicology
Aquatic weed control
Aquifer
Aquifer depletion
Aquifer restoration
Arable land
Aral Sea
Arco, Idaho
Arctic Council
Arctic haze
Arctic National Wildlife Refuge
Arid
Arid landscaping
Army Corps of Engineers
Arrhenius, Svante
Arsenic
Arsenic-treated lumber
Artesian well
Asbestos
Asbestos removal
Asbestosis
Ashio, Japan
Asian longhorn beetle
Asian (Pacific) shore crab
Asiatic black bear
Assimilative capacity
Francis of Assisi, St.
Asthma
Aswan High Dam
Atmosphere
Atmospheric (air) pollutants
Atmospheric deposition
Atmospheric inversion
Atomic Energy Commission
Atrazine
Attainment area
Audubon, John James
Australia
Autecology
Automobile
Automobile emissions
Autotroph
Avalanche

B

Bacillus thuringiensis
Background radiation
Bacon, Sir Francis
Baghouse
Balance of nature
Bald eagle
Barrier island
Basel Convention
Bass, Rick
Bats
Battery recycling
Bay of Fundy
Beach renourishment
Beattie, Mollie
Bellwether species
Below Regulatory Concern
Bennett, Hugh Hammond
Benzene
Benzo(a)pyrene
Berry, Wendell
Best available control technology
Best management practices
Best Practical Technology
Beta particle
Beyond Pesticides
Bhopal, India
Bikini atoll
Bioaccumulation
Bioaerosols
Bioassay
Bioassessment
Biochemical oxygen demand
Biodegradable
Biodiversity
Biofilms
Biofiltration
Biofouling
Biogeochemistry
Biogeography
Biohydrometallurgy
Bioindicator
Biological community
Biological fertility
Biological methylation
Biological Resources Division
Bioluminescence

Biomagnification
Biomass
Biomass fuel
Biome
Biophilia
Bioregional Project
Bioregionalism
Bioremediation
Biosequence
Biosphere
Biosphere reserve
Biotechnology
Bioterrorism
Biotic community
Biotoxins
Bioventing
BirdLife International
Birth defects
Bison
Black lung disease
Black-footed ferret
Blackout/brownout
Blow-out
Blue Angel
Blue revolution (fish farming)
Blue-baby syndrome
Bookchin, Murray
Borlaug, Norman E.
Boston Harbor clean up
Botanical garden
Boulding, Kenneth
Boundary Waters Canoe Area
Brackish
Bromine
Bronchitis
Brower, David Ross
Brown, Lester R.
Brown pelican
Brown tree snake
Browner, Carol
Brownfields
Brundtland, Gro Harlem
Btu
Budyko, Mikhail I.
Buffer
Bulk density
Burden of proof
Bureau of Land Management
Bureau of Oceans and International Environmental and Scientific Affairs (OES)
Bureau of Reclamation
Buried soil
Burroughs, John
Bush meat/market
Bycatch
Bycatch reduction devices

C

Cadmium
Cairo conference
Calcareous soil
Caldicott, Helen
Caldwell, Lynton Keith
California condor
Callicott, John Baird
Canadian Forest Service
Canadian Parks Service
Canadian Wildlife Service
Cancer
Captive propagation and reintroduction
Carbon
Carbon cycle
Carbon dioxide
Carbon emissions trading
Carbon monoxide
Carbon offsets (CO_2-emission offsets)
Carbon tax
Carcinogen
Carrying capacity
Carson, Rachel
Cash crop
Catalytic converter
Catskill watershed protection plan
Center for Environmental Philosophy
Center for Respect of Life and Environment
Center for Rural Affairs
Center for Science in the Public Interest
Centers for Disease Control and Prevention
Cesium 137
Chain reaction
Chaparral
Chelate
Chelyabinsk, Russia
Chemical bond
Chemical oxygen demand
Chemical spills
Chemicals
Chemosynthesis
Chernobyl Nuclear Power Station
Chesapeake Bay
Child survival revolution
Chimpanzees
Chipko Andolan movement
Chlordane
Chlorinated hydrocarbons
Chlorination
Chlorine
Chlorine monoxide
Chlorofluorocarbons

Cholera
Cholinesterase inhibitor
Chromatography
Chronic effects
Cigarette smoke
Citizen science
Citizens for a Better Environment
Clay minerals
Clay-hard pan
Clayoquot Sound
Clean Air Act (1963, 1970, 1990)
Clean coal technology
Clean Water Act (1972, 1977, 1987)
Clear-cutting
Clements, Frederic E.
Climate
Climax (ecological)
Clod
Cloning
Cloud chemistry
Club of Rome
C:N ratio
Coal
Coal bed methane
Coal gasification
Coal washing
Coase theorem
Coastal Society, The
Coastal Zone Management Act (1972)
Co-composting
Coevolution
Cogeneration
Cold fusion
Coliform bacteria
Colorado River
Combined Sewer Overflows
Combustion
Cometabolism
Commensalism
Commercial fishing
Commission for Environmental Cooperation
Commoner, Barry
Communicable diseases
Community ecology
Compaction
Comparative risk
Competition
Competitive exclusion
Composting
Comprehensive Environmental Response, Compensation, and Liability Act
Computer disposal
Condensation nuclei
Congo River and basin
Coniferous forest
Conservation
Conservation biology
Conservation easements
Conservation International
Conservation Reserve Program (CRP)
Conservation tillage
Consultative Group on International Agricultural Research
Container deposit legislation
Contaminated soil
Contour plowing
Convention on International Trade in Endangered Species of Wild Fauna and Flora (1975)
Convention on Long-Range Transboundary Air Pollution (1979)
Convention on the Conservation of Migratory Species of Wild Animals (1979)
Convention on the Law of the Sea (1982)
Convention on the Prevention of Marine Pollution by Dumping of Waste and Other Matter (1972)
Convention on Wetlands of International Importance (1971)
Conventional pollutant
Copper
Coprecipitation
Coral bleaching
Coral reef
Corporate Average Fuel Economy standards
Corrosion and material degradation
Cost-benefit analysis
Costle, Douglas M.
Council on Environmental Quality
Cousteau, Jacques-Yves
Cousteau Society, The
Coyote
Criteria pollutant
Critical habitat
Crocodiles
Cronon, William
Cross-Florida Barge Canal
Cruzen, Paul
Cryptosporidium
Cubatao, Brazil
Cultural eutrophication
Cuyahoga River
Cyclone collector

D

Dam removal
Dams (environmental effects)
Darling, Jay Norwood "Ding"
Darwin, Charles Robert
Dead zones
Debt for nature swap
Deciduous forest
Decline spiral

Decomposers
Decomposition
Deep ecology
Deep-well injection
Defenders of Wildlife
Defoliation
Deforestation
Delaney Clause
Demographic transition
Denitrification
Deoxyribose nucleic acid
Desalinization
Desert
Desert tortoise
Desertification
Design for disassembly
Detergents
Detoxification
Detritivores
Detritus
Dew point
Diazinon
Dichlorodiphenyl-trichloroethane
Dieback
Die-off
Dillard, Annie
Dioxin
Discharge
Disposable diapers
Dissolved oxygen
Dissolved solids
Dodo
Dolphins
Dominance
Dose response
Double-crested cormorants
Douglas, Marjory Stoneman
Drainage
Dredging
Drift nets
Drinking-water supply
Drip irrigation
Drought
Dry alkali injection
Dry cask storage
Dry cleaning
Dry deposition
Dryland farming
Dubos, René
Ducks Unlimited
Ducktown, Tennessee
Dunes and dune erosion
Dust Bowl

E

Earth Charter
Earth Day
Earth First!
Earth Island Institute
Earth Liberation Front
Earth Pledge Foundation
Earthquake
Earthwatch
Eastern European pollution
Ebola
Eco Mark
Ecocide
Ecofeminism
Ecojustice
Ecological consumers
Ecological economics
Ecological integrity
Ecological productivity
Ecological risk assessment
Ecological Society of America
Ecology
EcoNet
Economic growth and the environment
Ecosophy
Ecosystem
Ecosystem health
Ecosystem management
Ecoterrorism
Ecotone
Ecotourism
Ecotoxicology
Ecotype
Edaphic
Edaphology
Eelgrass
Effluent
Effluent tax
E_H
Ehrlich, Paul
El Niño
Electric utilities
Electromagnetic field
Electron acceptor and donor
Electrostatic precipitation
Elemental analysis
Elephants
Elton, Charles
Emergency Planning and Community Right-to-Know Act (1986)
Emergent diseases (human)
Emergent ecological diseases
Emission
Emission standards

Emphysema
Endangered species
Endangered Species Act (1973)
Endemic species
Endocrine disruptors
Energy and the environment
Energy conservation
Energy efficiency
Energy flow
Energy path, hard vs. soft
Energy policy
Energy recovery
Energy Reorganization Act (1973)
Energy Research and Development Administration
Energy taxes
Enteric bacteria
Environment
Environment Canada
Environmental accounting
Environmental aesthetics
Environmental auditing
Environmental chemistry
Environmental Defense
Environmental degradation
Environmental design
Environmental dispute resolution
Environmental economics
Environmental education
Environmental enforcement
Environmental engineering
Environmental estrogens
Environmental ethics
Environmental health
Environmental history
Environmental impact assessment
Environmental Impact Statement
Environmental law
Environmental Law Institute
Environmental liability
Environmental literacy and ecocriticism
Environmental monitoring
Environmental Monitoring and Assessment Program
Environmental policy
Environmental Protection Agency
Environmental racism
Environmental refugees
Environmental resources
Environmental science
Environmental stress
Environmental Stress Index
Environmental Working Group
Environmentalism
Environmentally Preferable Purchasing
Environmentally responsible investing
Enzyme
Ephemeral species
Epidemiology
Erodible
Erosion
Escherichia coli
Essential fish habitat
Estuary
Ethanol
Ethnobotany
Eurasian milfoil
European Union
Eutectic
Evapotranspiration
Everglades
Evolution
Exclusive Economic Zone
Exotic species
Experimental Lakes Area
Exponential growth
Externality
Extinction
Exxon Valdez

F

Family planning
Famine
Fauna
Fecundity
Federal Energy Regulatory Commission
Federal Insecticide, Fungicide and Rodenticide Act (1972)
Federal Land Policy and Management Act (1976)
Federal Power Commission
Feedlot runoff
Feedlots
Fertilizer
Fibrosis
Field capacity
Filters
Filtration
Fire ants
First World
Fish and Wildlife Service
Fish kills
Fisheries and Oceans Canada
Floatable debris
Flooding
Floodplain
Flora
Florida panther
Flotation
Flu pandemic
Flue gas
Flue-gas scrubbing
Fluidized bed combustion

Fluoridation
Fly ash
Flyway
Food additives
Food and Drug Administration
Food chain/web
Food irradiation
Food policy
Food waste
Food-borne diseases
Foot and mouth disease
Forbes, Stephen A.
Forel, Francois-Alphonse
Foreman, Dave
Forest and Rangeland Renewable Resources Planning Act (1974)
Forest decline
Forest management
Forest Service
Fossey, Dian
Fossil fuels
Fossil water
Four Corners
Fox hunting
Free riders
Freon
Fresh water ecology
Friends of the Earth
Frogs
Frontier economy
Frost heaving
Fuel cells
Fuel switching
Fugitive emissions
Fumigation
Fund for Animals
Fungi
Fungicide
Furans
Future generations

G

Gaia hypothesis
Galápagos Islands
Galdikas, Birute
Game animal
Game preserves
Gamma ray
Gandhi, Mohandas Karamchand
Garbage
Garbage Project
Garbology
Gasohol
Gasoline
Gasoline tax
Gastropods
Gene bank
Gene pool
Genetic engineering
Genetic resistance (or genetic tolerance)
Genetically engineered organism
Genetically modified organism
Geodegradable
Geographic information systems
Geological Survey
Georges Bank
Geosphere
Geothermal energy
Giant panda
Giardia
Gibbons
Gibbs, Lois
Gill nets
Glaciation
Gleason, Henry A.
Glen Canyon Dam
Global Environment Monitoring System
Global Forum
Global ReLeaf
Global Tomorrow Coalition
Goiter
Golf courses
Good wood
Goodall, Jane
Gore Jr., Albert
Gorillas
Grand Staircase-Escalante National Monument
Grasslands
Grazing on public lands
Great Barrier Reef
Great Lakes
Great Lakes Water Quality Agreement (1978)
Great Smoky Mountains
Green advertising and marketing
Green belt/greenway
Green Cross
Green packaging
Green plans
Green politics
Green products
Green Seal
Green taxes
Greenhouse effect
Greenhouse gases
Greenpeace
Greens
Grinevald, Jacques
Grizzly bear
Groundwater

Groundwater monitoring
Groundwater pollution
Growth curve
Growth limiting factors
Guano
Guinea worm eradication
Gulf War syndrome
Gullied land
Gypsy moth

H

Haagen-Smit, Arie Jan
Habitat
Habitat conservation plans
Habitat fragmentation
Haeckel, Ernst
Half-life
Halons
Hanford Nuclear Reservation
Hardin, Garrett
Hawaiian Islands
Hayes, Denis
Hazard Ranking System
Hazardous material
Hazardous Materials Transportation Act (1975)
Hazardous Substances Act (1960)
Hazardous waste
Hazardous waste site remediation
Hazardous waste siting
Haze
Heat (stress) index
Heavy metals and heavy metal poisoning
Heavy metals precipitation
Heilbroner, Robert L.
Hells Canyon
Henderson, Hazel
Herbicide
Heritage Conservation and Recreation Service
Hetch Hetchy Reservoir
Heterotroph
High-grading (mining, forestry)
High-level radioactive waste
High-solids reactor
Hiroshima, Japan
Holistic approach
Homeostasis
Homestead Act (1862)
Horizon
Horseshoe crabs
Household waste
Hubbard Brook Experimental Forest
Hudson River
Human ecology
Humane Society of the United States
Humanism
Human-powered vehicles
Humus
Hunting and trapping
Hurricane
Hutchinson, George E.
Hybrid vehicles
Hydrocarbons
Hydrochlorofluorocarbons
Hydrogen
Hydrogeology
Hydrologic cycle
Hydrology
Hydroponics
Hydrothermal vents

I

Ice age
Ice age refugia
Impervious material
Improvement cutting
Inbreeding
Incineration
Indicator organism
Indigenous peoples
Indonesian forest fires
Indoor air quality
Industrial waste treatment
Infiltration
INFORM
INFOTERRA (U.N. Environment Programme)
Injection well
Inoculate
Integrated pest management
Intergenerational justice
Intergovernmental Panel on Climate Change
Internalizing costs
International Atomic Energy Agency
International Cleaner Production Cooperative
International Convention for the Regulation of Whaling (1946)
International Geosphere-Biosphere Programme
International Institute for Sustainable Development
International Joint Commission
International Primate Protection League
International Register of Potentially Toxic Chemicals
International Society for Environmental Ethics
International trade in toxic waste
International Voluntary Standards
International Wildlife Coalition
Intrinsic value
Introduced species
Iodine 131
Ion

Ion exchange
Ionizing radiation
Iron minerals
Irrigation
Island biogeography
ISO 14000: International Environmental Management Standards
Isotope
Itai-itai disease
IUCN—The World Conservation Union
Ivory-billed woodpecker
Izaak Walton League

J

Jackson, Wes
James Bay hydropower project
Japanese logging

K

Kapirowitz Plateau
Kennedy Jr., Robert
Kepone
Kesterson National Wildlife Refuge
Ketones
Keystone species
Kirtland's warbler
Krakatoa
Krill
Krutch, Joseph Wood
Kudzu
Kwashiorkor
Kyoto Protocol/Treaty

L

La Nina
La Paz Agreement
Lagoon
Lake Baikal
Lake Erie
Lake Tahoe
Lake Washington
Land ethic
Land Institute
Land reform
Land stewardship
Land Stewardship Project
Land trusts
Land use
Landfill
Landscape ecology
Landslide
Land-use control
Latency
Lawn treatment
LD_{50}
Leaching
Lead
Lead management
Lead shot
Leafy spurge
League of Conservation Voters
Leakey, Louis
Leakey, Mary
Leakey, Richard E.
Leaking underground storage tank
Leopold, Aldo
Less developed countries
Leukemia
Lichens
Life cycle assessment
Limits to Growth (1972) and *Beyond the Limits* (1992)
Limnology
Lindeman, Raymond L.
Liquid metal fast breeder reactor
Liquified natural gas
Lithology
Littoral zone
Loading
Logging
Logistic growth
Lomborg, Bjørn
Lopez, Barry
Los Angeles Basin
Love Canal
Lovelock, Sir James Ephraim
Lovins, Amory B.
Lowest Achievable Emission Rate
Low-head hydropower
Low-level radioactive waste
Lyell, Charles
Lysimeter

M

MacArthur, Robert
Mad cow disease
Madagascar
Magnetic separation
Malaria
Male contraceptives
Man and the Biosphere Program
Manatees
Mangrove swamp
Marasmus
Mariculture
Marine ecology and biodiversity
Marine Mammals Protection Act (1972)
Marine pollution

Marine protection areas
Marine Protection, Research and Sanctuaries Act (1972)
Marine provinces
Marsh, George Perkins
Marshall, Robert
Mass burn
Mass extinction
Mass spectrometry
Mass transit
Material Safety Data Sheets
Materials balance approach
Maximum permissible concentration
McHarg, Ian
McKibben, Bill
Measurement and sensing
Medical waste
Mediterranean fruit fly
Mediterranean Sea
Megawatt
Mendes, Chico
Mercury
Metabolism
Metals, as contaminants
Meteorology
Methane
Methane digester
Methanol
Methyl tertiary butyl ether
Methylation
Methylmercury seed dressings
Mexico City, Mexico
Microbes (microorganisms)
Microbial pathogens
Microclimate
Migration
Milankovitch weather cycles
Minamata disease
Mine spoil waste
Mineral Leasing Act (1920)
Mining, undersea
Mirex
Mission to Planet Earth (NASA)
Mixing zones
Modeling (computer applications)
Molina, Mario
Monarch butterfly
Monkey-wrenching
Mono Lake
Monoculture
Monsoon
Montreal Protocol on Substances That Deplete the Ozone Layer (1987)
More developed country
Mortality
Mount Pinatubo
Mount St. Helens
Muir, John
Mulch
Multiple chemical sensitivity
Multiple Use-Sustained Yield Act (1960)
Multi-species management
Municipal solid waste
Municipal solid waste composting
Mutagen
Mutation
Mutualism
Mycorrhiza
Mycotoxin

ADVISORY BOARD

A number of recognized experts in the library and environmental communities provided invaluable assistance in the formulation of this encyclopedia. Our panel of advisors helped us shape this publication into its final form, and we would like to express our sincere appreciation to them:

Dean Abrahamson: Hubert H. Humphrey Institute of Public Affairs, University of Minnesota, Minneapolis, Minnesota

Maria Jankowska: Library, University of Idaho, Moscow, Idaho

Terry Link: Library, Michigan State University, East Lansing, Michigan

Holmes Rolston: Department of Philosophy, Colorado State University, Fort Collins, Colorado

Frederick W. Stoss: Science and Engineering Library, State University of New York—Buffalo, Buffalo, New York

Hubert J. Thompson: Conrad Sulzer Regional Library, Chicago, Illinois

HOW TO USE THIS BOOK

- The third edition of *Environmental Encyclopedia* has been designed with ready reference in mind.
- Straight **alphabetical arrangement** of topics allows users to locate information quickly.
- **Bold-faced terms** within entries direct the reader to related articles.
- **Contact information** is given for each organization profiled in the book.
- **Cross-references** at the end of entries alert readers to related entries not specifically mentioned in the body of the text.
- The **Resources** sections direct readers to additional sources of information on a topic.
- **Three appendices** provide the reader with a chronology of environmental events, a summary of environmental legislation, and a succinct alphabetical list of environmental organizations.
- A comprehensive **general index** guides readers to all topics mentioned in the text.

This Page Intentionally Left Blank

INTRODUCTION

Welcome to the third edition of the Gale *Environmental Encyclopedia*! Those of us involved in writing and production of this book hope you will find the material here interesting and useful. As you might imagine, choosing what to include and what to exclude from this collection has been challenging. Almost everything has some environmental significance, so our task has been to select a limited number of topics we think are of greatest importance in understanding our environment and our relation to it. Undoubtedly, we have neglected some topics that interest you and included some you may consider irrelevant, but we hope that overall you will find this new edition helpful and worthwhile.

The word environment is derived from the French *environ*, which means to "encircle" or "surround." Thus, our environment can be defined as the physical, chemical, and biological world that envelops us, as well as the complex of social and cultural conditions affecting an individual or community. This broad definition includes both the natural world and the "built" or technological environment, as well as the cultural and social contexts that shape human lives. You will see that we have used this comprehensive meaning in choosing the articles and definitions contained in this volume.

Among some central concerns of environmental science are:

- how did the natural world on which we depend come to be as it is, and how does it work?
- what have we done and what are we now doing to our environment—both for good and ill?
- what can we do to ensure a sustainable future for ourselves, future generations, and the other species of organisms on which—although we may not be aware of it—our lives depend?

The articles in this volume attempt to answer those questions from a variety of different perspectives.

Historically, environmentalism is rooted in natural history, a search for beauty and meaning in nature. Modern environmental science expands this concern, drawing on almost every area of human knowledge including social sciences, humanities, and the physical sciences. Its strongest roots, however, are in ecology, the study of interrelationships among and between organisms and their physical or nonliving environment. A particular strength of the ecological approach is that it studies systems holistically; that is, it looks at interconnections that make the whole greater than the mere sum of its parts. You will find many of those interconnections reflected in this book. Although the entries are presented individually so that you can find topics easily, you will notice that many refer to other topics that, in turn, can lead you on through the book if you have time to follow their trail. This series of linkages reflects the multilevel associations in environmental issues.

As our world becomes increasingly interrelated economically, socially, and technologically, we find evermore evidence that our global environment is also highly interconnected. In 2002, the world population reached about 6.2 billion people, more than triple what it had been a century earlier. Although the rate of population growth is slowing—having dropped from 2.0% per year in 1970 to 1.2% in 2002—we are still adding about 200,000 people per day, or about 75 million per year. Demographers predict that the world population will reach 8 or 9 billion before stabilizing sometime around the middle of this century. Whether natural resources can support so many humans is a question of great concern.

In preparation for the third global summit in South Africa, the United Nations released several reports in 2002 outlining the current state of our environment. Perhaps the greatest environmental concern as we move into the twenty-first century is the growing evidence that human activities are causing global climate change. Burning of fossil fuels in power plants, vehicles, factories, and homes release carbon dioxide into the atmosphere. Burning forests and crop residues, increasing cultivation of paddy rice, raising billions of ruminant animals, and other human activities also add to the rapidly growing atmospheric concentrations of heat trapping gases in the atmosphere. Global temperatures have begun

to rise, having increased by about 1°F (0.6°C) in the second half of the twentieth century. Meteorologists predict that over the next 50 years, the average world temperature is likely to increase somewhere between 2.7–11°F (1.5–6.1°C). That may not seem like a very large change, but the difference between current average temperatures and the last ice age, when glaciers covered much of North America, was only about 10°F (5°C).

Abundant evidence is already available that our climate is changing. The twentieth century was the warmest in the last 1,000 years; the 1990s were the warmest decade, and 2002 was the single warmest year of the past millennium. Glaciers are disappearing on every continent. More than half the world's population depends on rivers fed by alpine glaciers for their drinking water. Loss of those glaciers could exacerbate water supply problems in areas where water is already scarce. The United Nations estimates that 1.1 billion people—one-sixth of the world population—now lack access to clean water. In 25 years, about two-thirds of all humans will live in water-stressed countries where supplies are inadequate to meet demand.

Spring is now occurring about a week earlier and fall is coming about a week later over much of the northern hemisphere. This helps some species, but is changing migration patterns and home territories for others. In 2002, early melting of ice floes in Canada's Gulf of St. Lawrence apparently drowned nearly all of the 200,000 to 300,000 harp seal pups normally born there. Lack of sea ice is also preventing polar bears from hunting seals. Environment Canada reports that polar bears around Hudson's Bay are losing weight and decreasing in number because of poor hunting conditions. In 2002, a chunk of ice about the size of Rhode Island broke off the Larsen B ice shelf on the Antarctic Peninsula. As glacial ice melts, ocean levels are rising, threatening coastal ecosystems and cities around the world.

After global climate change, perhaps the next greatest environmental concern for most biologists is the worldwide loss of biological diversity. Taxonomists warn that one-fourth of the world's species could face extinction in the next 30 years. Habitat destruction, pollution, introduction of exotic species, and excessive harvesting of commercially important species all contribute to species losses. Millions of species—most of which have never even been named by science, let alone examined for potential usefulness in medicine, agriculture, science, or industry—may disappear in the next century as a result of our actions. We know little about the biological roles of these organisms in the ecosystems and their loss could result in an ecological tragedy.

Ecological economists have tried to put a price on the goods and services provided by natural ecosystems. Although many ecological processes aren't traded in the market place, we depend on the natural world to do many things for us like purifying water, cleansing air, and detoxifying our wastes. How much would it cost if we had to do all this ourselves? The estimated annual value of all ecological goods and services provided by nature are calculated to be worth at least $33 trillion, or about twice the annual GNPs of all national economies in the world. The most valuable ecosystems in terms of biological processes are wetlands and coastal estuaries because of their high level of biodiversity and their central role in many biogeochemical cycles.

Already there are signs that we are exhausting our supplies of fertile soil, clean water, energy, and biodiversity that are essential for life. Furthermore, pollutants released into the air and water, along with increasing amounts of toxic and hazardous wastes created by our industrial society, threaten to damage the ecological life support systems on which all organisms—including humans—depend. Even without additional population growth, we may need to drastically rethink our patterns of production and disposal of materials if we are to maintain a habitable environment for ourselves and our descendants.

An important lesson to be learned from many environmental crises is that solving one problem often creates another. Chlorofluorocarbons, for instance, were once lauded as a wonderful discovery because they replaced toxic or explosive chemicals then in use as refrigerants and solvents. No one anticipated that CFCs might damage stratospheric ozone that protects us from dangerous ultraviolet radiation. Similarly, the building of tall smokestacks on power plants and smelters lessened local air pollution, but spread acid rain over broad areas of the countryside. Because of our lack of scientific understanding of complex systems, we are continually subjected to surprises. How to plan for "unknown unknowns" is an increasing challenge as our world becomes more tightly interconnected and our ability to adjust to mistakes decreases.

Not all is discouraging, however, in the field of environmental science. Although many problems beset us, there are also encouraging signs of progress. Some dramatic successes have occurred in wildlife restoration and habitat protection programs, for instance. The United Nations reports that protected areas have increased five-fold over the past 30 years to nearly 5 million square miles. World forest losses have slowed, especially in Asia, where deforestation rates slowed from 8% in the 1980s to less than 1% in the 1990s. Forested areas have actually increased in many developed countries, providing wildlife habitat, removal of excess carbon dioxide, and sustainable yields of forest products.

In spite of dire warnings in the 1960s that growing human populations would soon overshoot the earth's carrying capacity and result in massive famines, food supplies have more than kept up with population growth. There is

more than enough food to provide a healthy diet for everyone now living, although inequitable distribution leaves about 800 million with an inadequate diet. Improved health care, sanitation, and nutrition have extended life expectancies around the world from 40 years, on average, a century ago, to 65 years now. Public health campaigns have eradicated smallpox and nearly eliminated polio. Other terrible diseases have emerged, however, most notably acquired immunodeficiency syndrome (AIDS), which is now the fourth most common cause of death worldwide. Forty million people are now infected with HIV—70% percent of them in sub-Saharan Africa—and health experts warn that unsanitary blood donation practices and spreading drug use in Asia may result in tens of millions more AIDS deaths in the next few decades.

In developed countries, air and pollution have decreased significantly over the past 30 years. In 2002, the Environmental Protection Agency declared that Denver—which once was infamous as one of the most polluted cities in the United States—is the first major city to meet all the agency's standards for eliminating air pollution. At about the same time, the EPA announced that 91% of all monitored river miles in the United States met the water quality goals set in the 1985 clean water act. Pollution-sensitive species like mayflies have returned to the upper Mississippi River, and in Britian, salmon are being caught in the Thames River after being absent for more than two centuries.

Conditions aren't as good, however, in many other countries. In most of Latin America, Africa, and Asia, less than two % of municipal sewage is given even primary treatment before being dumped into rivers, lakes, or the ocean. In South Asia, a 2-mile (3-km) thick layer of smog covers the entire Indian sub-continent for much of the year. This cloud blocks sunlight and appears to be changing the climate, bringing drought to Pakistan and Central Asia, and shifting monsoon winds that caused disastrous floods in 2002 in Nepal, Bangladesh, and eastern India that forced 25 million people from their homes and killed at least 1,000 people. Nobel laureate Paul Crutzen estimates that two million deaths each year in India alone can be attributed to air pollution effects.

After several decades of struggle, a world-wide ban on the "dirty dozen" most dangerous persistent organic pollutants (POPs) was ratified in 2000. Elimination of compounds such as DDT, Aldrin, Dieldrin, Mirex, Toxaphene, polychlorinated biphenyls, and dioxins has allowed recovery of several wildlife species including bald eagles, perigrine falcons, and brown pelicans. Still, other toxic synthetic chemicals such as polybrominated diphenyl ethers, chromated copper arsenate, perflurooctane sulfonate, and atrazine are now being found accumulating in food chains far from anyplace where they have been used.

Solutions for many of our pollution problems can be found in either improved technology, more personal responsibility, or better environmental management. The question is often whether we have the political will to enforce pollution control programs and whether we are willing to sacrifice short-term convenience and affluence for long-term ecological stability. We in the richer countries of the world have become accustomed to a highly consumptive lifestyle. Ecologists estimate that humans either use directly, destroy, co-opt, or alter almost 40% of terrestrial plant productivity, with unknown consequences for the biosphere. Whether we will be willing to leave some resources for other species and future generations is a central question of environmental policy.

One way to extend resources is to increase efficiency and recycling of the items we use. Automobiles have already been designed, for example, that get more than 100 mi/gal (42 km/l) of diesel fuel and are completely recyclable when they reach the end of their designed life. Although recycling rates in the United States have increased in recent years, we could probably double our current rate with very little sacrifice in economics or convenience. Renewable energy sources such as solar or wind power are making encouraging progress. Wind already is cheaper than any other power source except coal in many localities. Solar energy is making it possible for many of the two billion people in the world who don't have access to electricity to enjoy some of the benefits of modern technology. Worldwide, the amount of installed wind energy capacity more than doubled between 1998 and 2002. Germany is on course to obtain 20% of its energy from renewables by 2010. Together, wind, solar, biomass and other forms of renewable energy have the potential to provide thousands of times as much energy as all humans use now. There is no reason for us to continue to depend on fossil fuels for the majority of our energy supply.

One of the widely advocated ways to reduce poverty and make resources available to all is sustainable development. A commonly used definition of this term is given in *Our Common Future*, the report of the World Commission on Environment and Development (generally called the Brundtland Commission after the prime minister of Norway, who chaired it), described sustainable development as: "meeting the needs of the present without compromising the ability of future generations to meet their own needs." This implies improving health, education, and equality of opportunity, as well as ensuring political and civil rights through jobs and programs based on sustaining the ecological base, living on renewable resources rather than nonrenewable ones, and living within the carrying capacity of supporting ecological systems.

Several important ethical considerations are embedded in environmental questions. One of these is intergenerational

justice: what responsibilities do we have to leave resources and a habitable planet for future generations? Is our profligate use of fossil fuels, for example, justified by the fact that we have technology to extract fossil fuels and enjoy their benefits? Will human lives in the future be impoverished by the fact that we have used up most of the easily available oil, gas, and coal? Author and social critic Wendell Berry suggests that our consumption of these resources constitutes a theft of the birthright and livelihood of posterity. Philosopher John Rawls advocates a "just savings principle" in which members of each generation may consume no more than their fair share of scarce resources.

How many generations are we obliged to plan for and what is our "fair share?" It is possible that our use of resources now—inefficient and wasteful as it may be—represents an investment that will benefit future generations. The first computers, for instance, were huge clumsy instruments that filled rooms full of expensive vacuum tubes and consumed inordinate amounts of electricity. Critics complained that it was a waste of time and resources to build these enormous machines to do a few simple calculations. And yet if this technology had been suppressed in its infancy, the world would be much poorer today. Now nanotechnology promises to make machines and tools in infinitesimal sizes that use minuscule amounts of materials and energy to carry out valuable functions. The question remains whether future generations will be glad that we embarked on the current scientific and technological revolution or whether they will wish that we had maintained a simple agrarian, Arcadian way of life.

Another ethical consideration inherent in many environmental issues is whether we have obligations or responsibilities to other species or to Earth as a whole. An anthropocentric (human-centered) view holds that humans have rightful dominion over the earth and that our interests and well-being take precedence over all other considerations. Many environmentalists criticize this perspective, considering it arrogant and destructive. Biocentric (life-centered) philosophies argue that all living organisms have inherent values and rights by virtue of mere existence, whether or not they are of any use to us. In this view, we have a responsibility to leave space and resources to enable other species to survive and to live as naturally as possible. This duty extends to making reparations or special efforts to encourage the recovery of endangered species that are threatened with extinction due to human activities.Some environmentalists claim that we should adopt an ecocentric (ecologically centered) outlook that respects and values nonliving entities such as rocks, rivers, mountains—even whole ecosystems—as well as other living organisms. In this view, we have no right to break up a rock, dam a free-flowing river, or reshape a landscape simply because it benefits us. More importantly, we should conserve and maintain the major ecological processes that sustain life and make our world habitable.

Others argue that our existing institutions and understandings, while they may need improvement and reform, have provided us with many advantages and amenities. Our lives are considerably better in many ways than those of our ancient ancestors, whose lives were, in the words of British philosopher Thomas Hobbes: "nasty, brutish, and short." Although science and technology have introduced many problems, they also have provided answers and possible alternatives as well.

It may be that we are at a major turning point in human history. Current generations are in a unique position to address the environmental issues described in this encyclopedia. For the first time, we now have the resources, motivation, and knowledge to protect our environment and to build a sustainable future for ourselves and our children. Until recently, we didn't have these opportunities, or there was not enough clear evidence to inspire people to change their behavior and invest in environmental protection; now the need is obvious to nearly everyone. Unfortunately, this also may be the last opportunity to act before our problems become irreversible.

We hope that an interest in preserving and protecting our common environment is one reason that you are reading this encyclopedia and that you will find information here to help you in that quest.

[*William P. Cunningham, Managing Editor*]

A

Edward Paul Abbey (1927 – 1989)

American environmentalist and writer

Novelist, essayist, white-water rafter, and self-described "desert rat," Abbey wrote of the wonders and beauty of the American West that was fast disappearing in the name of "development" and "progress." Often angry, frequently funny, and sometimes lyrical, Abbey recreated for his readers a region that was unique in the world. The American West was perhaps the last place where solitary selves could discover and reflect on their connections with wild things and with their fellow human beings.

Abbey was born in Home, Pennsylvania, in 1927. He received his B.A. from the University of New Mexico in 1951. After earning his master's degree in 1956, he joined the **National Park Service**, where he served as park ranger and fire fighter. He later taught writing at the University of Arizona.

Abbey's books and essays, such as *Desert Solitaire* (1968) and *Down the River* (1982), had their angrier fictional counterparts—most notably, *The Monkey Wrench Gang* (1975) and *Hayduke Lives!* (1990)—in which he gave voice to his outrage over the destruction of deserts and rivers by dam-builders and developers of all sorts. In *The Monkey Wrench Gang* Abbey weaves a tale of three "ecoteurs" who defend the wild west by destroying the means and machines of development—dams, bulldozers, **logging** trucks—which would otherwise reduce forests to lumber and raging rivers to **irrigation** channels.

This aspect of Abbey's work inspired some radical environmentalists, including **Dave Foreman** and other members of **Earth First!**, to practice "monkey-wrenching" or "ecotage" to slow or stop such environmentally destructive practices as **strip mining**, the **clear-cutting** of old-growth forests on **public land**, and the damming of wild rivers for flood control, hydroelectric power, and what Abbey termed "industrial tourism." Although Abbey's description and defense of such tactics has been widely condemned by many mainstream environmental groups, he remains a revered figure among many who believe that gradualist tactics have not succeeded in slowing, much less stopping, the destruction of North American **wilderness**. Abbey is unique among environmental writers in having an oceangoing ship named after him. One of the vessels in the fleet of the militant **Sea Shepherd Conservation Society**, the *Edward Abbey*, rams and disables **whaling** and drift-net fishing vessels operating illegally in international waters. Abbey would have welcomed the tribute and, as a white-water rafter and canoeist, would no doubt have enjoyed the irony.

Abbey died on March 14, 1989. He is buried in a **desert** in the southwestern United States.

Absorption

Absorption, or more generally "sorption," is the process by which one material (the sorbent) takes up and retains another (the sorbate) to form a homogenous concentration at equilibrium.

The general term is "sorption," which is defined as adhesion of gas molecules, dissolved substances, or liquids to the surface of solids with which they are in contact. In soils, three types of mechanisms, often working together, constitute **sorption**. They can be grouped into physical sorp-

tion, chemiosorption, and penetration into the solid mineral phase. Physical sorption (also known as **adsorption**) involves the attachment of the sorbent and sorbate through weak atomic and molecular forces. Chemiosorption involves chemical bonds similar to holding atoms in a molecule. Electrostatic forces operate to bond minerals via **ion exchange**, such as the replacement of sodium, magnesium, potassium, and **aluminum** cations (+) as exchangeable bases with **acid** (-) soils. While cation (positive **ion**) exchange is the dominant exchange process occurring in soils, some soils have the ability to retain anions (negative ions) such as **nitrates**, **chlorine** and, to a larger extent, oxides of sulfur.

Absorption and Wastewater Treatment

In on-site **wastewater** treatment, the **soil** absorption field is the land area where the wastewater from the **septic tank** is spread into the soil. One of the most common types of soil absorption field has porous plastic pipe extending away from the distribution box in a series of two or more parallel trenches, usually 1.5–2 ft (30.5–61 cm) wide. In conventional, below-ground systems, the trenches are 1.5–2 ft deep. Some absorption fields must be placed at a shallower depth than this to compensate for some limiting soil condition, such as a hardpan or high **water table**. In some cases they may even be placed partially or entirely in fill material that has been brought to the lot from elsewhere.

The porous pipe that carries wastewater from the distribution box into the absorption field is surrounded by gravel that fills the trench to within a foot or so of the ground surface. The gravel is covered by fabric material or building paper to prevent plugging. Another type of drainfield consists of pipes that extend away from the distribution box, not in trenches but in a single, gravel-filled bed that has several such porous pipes in it. As with trenches, the gravel in a bed is covered by fabric or other porous material.

Usually the wastewater flows gradually downward into the gravel-filled trenches or bed. In some instances, such as when the septic tank is lower than the drainfield, the wastewater must be pumped into the drainfield. Whether gravity flow or pumping is used, wastewater must be evenly distributed throughout the drainfield. It is important to ensure that the drainfield is installed with care to keep the porous pipe level, or at a very gradual downward slope away from the distribution box or pump chamber, according to specifications stipulated by public health officials. Soil beneath the gravel-filled trenches or bed must be **permeable** so that wastewater and air can move through it and come in contact with each other. Good **aeration** is necessary to ensure that the proper chemical and microbiological processes will be occurring in the soil to cleanse the percolating wastewater of contaminants. A well-aerated soil also ensures slow travel and good contact between wastewater and soil.

How Common Are Septic Systems with Soil Absorption Systems?

According to the 1990 U.S. Census, there are about 24.7 million households in the United States that use septic tank systems or cesspools (holes or pits for receiving sewage) for wastewater treatment. This figure represents roughly 24% of the total households included in the census.

According to a review of local health department information by the National Small Flows Clearinghouse, 94% of participating health departments allow or permit the use of septic tank and soil absorption systems. Those that do not allow septic systems have sewer lines available to all residents. The total volume of waste disposed of through septic systems is more than one trillion gallons (3.8 trillion l) per year, according to a study conducted by the U.S. Environmental Protection Agency's Office of Technology Assessment, and virtually all of that waste is discharged directly to the subsurface, which affects **groundwater** quality.

Acclimation

Acclimation is the process by which an organism adjusts to a change in its **environment**. It generally refers to the ability of living things to adjust to changes in **climate**, and usually occurs in a short time of the change.

Scientists distinguish between acclimation and acclimatization because the latter adjustment is made under natural conditions when the organism is subject to the full range of changing environmental factors. Acclimation, however, refers to a change in only one environmental factor under laboratory conditions.

In an acclimation experiment, adult **frogs** (*Rana temporaria*) maintained in the laboratory at a temperature of either 50°F (10°C) or 86°F (30°C) were tested in an environment of 32°F (0°C). It was found that the group maintained at the higher temperature was inactive at freezing. The group maintained at 50°F (10°C), however, was active at the lower temperature; it had acclimated to the lower temperature.

Acclimation and acclimatization can have profound effects upon behavior, inducing shifts in preferences and in mode of life. The golden hamster (*Mesocricetus auratus*) prepares for hibernation when the environmental temperature drops below 59°F (15°C). Temperature preference tests in the laboratory show that the hamsters develop a marked preference for cold environmental temperatures during the pre-hibernation period. Following arousal from a simulated period of hibernation, the situation is reversed, and the hamsters actively prefer the warmer environments.

An acclimated microorganism is any microorganism that is able to adapt to environmental changes such as a change in temperature or a change in the quantity of oxygen or other gases. Many organisms that live in environments with seasonal changes in temperature make physiological adjustments that permit them to continue to function normally, even though their environmental temperature goes through a definite annual temperature cycle.

Acclimatization usually involves a number of interacting physiological processes. For example, in acclimatizing to high altitudes, the first response of human beings is to increase their breathing rate. After about 40 hours, changes have occurred in the oxygen-carrying capacity of the blood, which makes it more efficient in extracting oxygen at high altitudes. As this occurs, the breathing rate returns to normal.

Accounting for nature

A new approach to national income accounting in which the degradation and depletion of natural resource stocks and environmental amenities are explicitly included in the calculation of net national product (NNP). NNP is equal to gross national product (GNP) minus capital depreciation, and GNP is equal to the value of all final goods and services produced in a nation in a particular year. It is recognized that **natural resources** are economic assets that generate income, and that just as the depreciation of buildings and capital equipment are treated as economic costs and subtracted from GNP to get NNP, depreciation of *natural capital* should also be subtracted when calculating NNP. In addition, expenditures on environmental protection, which at present are included in GNP and NNP, are considered defensive expenditures in accounting for **nature** which should not be included in either GNP or NNP.

Accuracy

Accuracy is the closeness of an experimental measurement to the "true value" (i.e., actual or specified) of a measured quantity. A "true value" can determined by an experienced analytical scientist who performs repeated analyses of a sample of known purity and/or concentration using reliable, well-tested methods.

Measurement is inexact, and the magnitude of that exactness is referred to as the error. Error is inherent in measurement and is a result of such factors as the **precision** of the measuring tools, their proper adjustment, the method, and competency of the analytical scientist.

Statistical methods are used to evaluate accuracy by predicting the likelihood that a result varies from the "true value." The analysis of probable error is also used to examine the suitability of methods or equipment used to obtain, portray, and utilize an acceptable result. Highly accurate data can be difficult to obtain and costly to produce. However, different applications can require lower levels of accuracy that are adequate for a particular study.

Acetone

Acetone (C_3H_60) is a colorless liquid that is used as a solvent in products, such as in nail polish and paint, and in the manufacture of other **chemicals** such as **plastics** and fibers. It is a naturally occurring compound that is found in plants and is released during the **metabolism** of fat in the body. It is also found in volcanic gases, and is manufactured by the chemical industry. Acetone is also found in the **atmo-**

The basic mechanisms of acid deposition. (Illustration by Wadsworth Inc. Reproduced by permission.)

sphere as an oxidation product of both natural and **anthropogenic** volatile organic compounds (VOCs). It has a strong smell and taste, and is soluble in water. The evaporation point of acetone is quite low compared to water, and the chemical is highly flammable. Because it is so volatile, the acetone manufacturing process results in a large percentage of the compound entering the atmosphere. Ingesting acetone can cause damage to the tissues in the mouth and can lead to unconsciousness. Breathing acetone can cause irritation of the eyes, nose, and throat; headaches; dizziness; nausea; unconsciousness; and possible coma and death. Women may experience menstrual irregularity. There has been concern about the carcinogenic nature of acetone, but laboratory studies, and studies of humans who have been exposed to acetone in the course of their occupational activities show no evidence that acetone causes **cancer**.

[*Marie H. Bundy*]

Acid and base

According to the definition used by environmental chemists, an acid is a substance that increases the **hydrogen ion** (H^+) concentration in a solution and a base is a substance that removes hydrogen ions (H^+) from a solution. In water, removal of hydrogen ions results in an increase in the hydroxide ion (OH^-) concentration. Water with a **pH** of 7.0 is neutral, while lower pH values are acidic and higher pH values are basic.

Acid deposition

Acid precipitation from the **atmosphere**, whether in the form of dryfall (finely divided acidic salts), rain, or snow. Naturally occurring carbonic acid normally makes rain and snow mildly acidic (approximately 5.6 **pH**). Human activities often introduce much stronger and more damaging acids. Sulfuric acids formed from sulfur oxides released in **coal** or oil **combustion** or smelting of sulfide ores predominate as the major atmospheric acid in industrialized areas. Nitric acid created from **nitrogen oxides**, formed by oxidizing atmospheric **nitrogen** when any fuel is burned in an oxygen-rich **environment**, constitutes the major source of acid precipitation in such cities as Los Angeles with little industry,

but large numbers of trucks and automobiles. The damage caused to building materials, human health, crops, and natural ecosystems by atmospheric acids amounts to billions of dollars per year in the United States.

Acid mine drainage

The process of mining the earth for **coal** and metal ores has a long history of rich economic rewards—and a high level of environmental impact to the surrounding aquatic and terrestrial ecosystems. Acid mine **drainage** is the highly acidic, sediment-laden **discharge** from exposed mines that is released into the ambient aquatic **environment**. In large areas of Pennsylvania, West Virginia, and Kentucky, the bright orange seeps of acid mine drainage have almost completely eliminated aquatic life in streams and ponds that receive the discharge. In the Appalachian coal mining region, almost 7,500 mi (12,000 km) of streams and almost 30,000 acres (12,000 ha) of land are estimated to be seriously affected by the discharge of uncontrolled acid mine drainage.

In the United States, coal-bearing geological strata occur near the surface in large portions of the Appalachian mountain region. The relative ease with which coal could be extracted from these strata led to a type of mining known as **strip mining** that was practiced heavily in the nineteenth and early twentieth centuries. In this process, large amounts of earth, called the **overburden**, were physically removed from the surface to expose the coal-bearing layer beneath. The coal was then extracted from the rock as quickly and cheaply as possible. Once the bulk of the coal had been mined, and no more could be extracted without a huge additional cost, the sites were usually abandoned. The remnants of the exhausted coal-bearing rock and **soil** are called the **mine spoil waste**.

Acid mine drainage is not generated by strip mining itself but by the nature of the rock where it takes place. Three conditions are necessary to form acid mine drainage: pyrite-bearing rock, oxygen, and iron-oxidizing bacteria. In the Appalachians, the coal-bearing rocks usually contain significant quantities of pyrite (iron). This compound is normally not exposed to the **atmosphere** because it is buried underground within the rock; it is also insoluble in water. The iron and the sulfide are said to be in a reduced state, i.e., the iron atom has not released all the electrons that it is capable of releasing. When the rock is mined, the pyrite is exposed to air. It then reacts with oxygen to form ferrous iron and sulfate ions, both of which are highly soluble in water. This leads to the formation of sulfuric acid and is responsible for the acidic nature of the drainage. But the oxidation can only occur if the bacteria *Thiobacillus ferrooxidans* are present. These activate the iron-and-sulfur oxidizing reactions, and use the energy released during the reactions for their own growth. They must have oxygen to carry these reactions through. Once the maximum oxidation is reached, these bacteria can derive no more energy from the compounds and all reactions stop.

The acidified water may be formed in several ways. It may be generated by rain falling on exposed mine spoils waste or when rain and surface water (carrying **dissolved oxygen**) flow down and seep into rock fractures and mine shafts, coming into contact with pyrite-bearing rock. Once the acidified water has been formed, it leaves the mine area as seeps or small streams.

Characteristically bright orange to rusty red in color due to the iron, the liquid may be at a pH of 2–4. These are extremely low pH values and signify a very high degree of acidity. Vinegar, for example, has a pH of about 4.7 and the pH associated with **acid rain** is in the range of 4–6. Thus, acid mine drainage with a pH of 2 is more acidic than almost any other naturally occurring liquid release in the environment (with the exception of some volcanic lakes that are pure acid). Usually, the drainage is also very high in dissolved iron, manganese, **aluminum**, and suspended solids.

The acidic drainage released from the mine **spoil** wastes usually follows the natural **topography** of its area and flows into the nearest streams or **wetlands** where its effect on the **water quality** and **biotic community** is unmistakable. The iron coats the stream bed and its vegetation as a thick orange coating that prevents sunlight from penetrating leaves and plant surfaces. **Photosynthesis** stops and the vegetation (both vascular plants and algae) dies. The acid drainage eventually also makes the receiving water acid. As the pH drops, the fish, the invertebrates, and algae die when their **metabolism** can no longer adapt. Eventually, there is no life left in the stream with the possible exception of some bacteria that may be able to tolerate these conditions. Depending on the number and volume of seeps entering a stream and the volume of the stream itself, the area of impact may be limited and improved conditions may exist downstream, as the acid drainage is diluted. Abandoned mine spoil areas also tend to remain barren, even after decades. The colonization of the acidic mineral soil by plant **species** is a slow and difficult process, with a few **lichens** and aspens being the most hardy species to establish.

While many methods have been tried to control or mitigate the effects of acid mine drainage, very few have been successful. Federal mining regulations (**Surface Mining Control and Reclamation Act** of 1978) now require that when mining activity ceases, the mine spoil waste should be buried and covered with the overburden and vegetated **topsoil**. The intent is to restore the area to premining condition and to prevent the generation of acid mine drainage by

limiting the exposure of pyrite to oxygen and water. Although some minor seeps may still occur, this is the single-most effective way to minimize the potential scale of the problem. Mining companies are also required to monitor the effectiveness of their restoration programs and must post bonds to guarantee the execution of abatement efforts, should any become necessary in the future.

There are, however, numerous abandoned sites exposing pyrite-bearing spoils. Cleanup efforts for these sites have focused on controlling one or more of the three conditions necessary for the creation of the acidity: pyrite, bacteria, and oxygen. Attempts to remove bulk quantities of the pyrite-bearing mineral and store it somewhere else are extremely expensive and difficult to execute. Inhibiting the bacteria by using **detergents**, solvents, and other bactericidal agents are temporarily effective, but usually require repeated application. Attempts to seal out air or water are difficult to implement on a large scale or in a comprehensive manner.

Since it is difficult to reduce the formation of acid mine drainage at abandoned sites, one of the most promising new methods of mitigation treats the acid mine drainage after it exits the mine spoil wastes. The technique channels the acid seeps through artificially created wetlands, planted with cattails or other wetland plants in a bed of gravel, limestone, or compost. The limestone neutralizes the acid and raises the pH of the drainage while the mixture of oxygen-rich and oxygen-poor areas within the wetland promote the removal of iron and other metals from the drainage. Currently, many agencies, universities, and private firms are working to improve the design and performance of these artificial wetlands. A number of additional treatment techniques may be strung together in an interconnected system of anoxic limestone trenches, settling ponds, and planted wetlands. This provides a variety of physical and chemical microenvironments so that each undesirable characteristic of the acid drainage can be individually addressed and treated, e.g., acidity is neutralized in the trenches, suspended solids are settled in the ponds, and metals are precipitated in the wetlands. In the United States, the research and treatment of acid mine drainage continues to be an active field of study in the Appalachians and in the metal-mining areas of the Rocky Mountains.

Acid rain

Acid rain is the term used in the popular press that is equivalent to acidic deposition as used in the scientific literature. **Acid deposition** results from the deposition of airborne acidic pollutants on land and in bodies of water. These pollutants can cause damage to forests as well as to lakes and streams.

The major pollutants that cause acidic deposition are **sulfur dioxide** (SO_2) and **nitrogen oxides** (NO_x) produced during the **combustion** of **fossil fuels**. In the **atmosphere** these gases oxidize to sulfuric acid (H_2SO_4) and nitric acid (HNO_3) that can be transported long distances before being returned to the earth dissolved in rain drops (wet deposition), deposited on the surfaces of plants as cloud droplets, or directly on plant surfaces (**dry deposition**). Electrical utilities contribute 70% of the 20 million tons (21 million metric tons) of SO_2 that are annually added to the atmosphere. Most of this is from the combustion of **coal**. **Electric utilities** also contribute 30% of the 19 million tons of NO_x added to the atmosphere, and internal combustion engines used in automobiles, trucks, and buses contribute more than 40%. Natural sources such as forest fires, swamp gases, and volcanoes only contribute 1–5% of atmospheric SO_2. Forest fires, lightning, and microbial processes in soils contribute about 11% to atmospheric NO_x. In response to **air quality** regulations, electrical utilities have switched to coal with lower sulfur content and installed scrubbing systems to remove SO_2. This has resulted in a steady decrease in SO_2 emissions in the United States since 1970, with a 18–20% decrease between 1975 and 1988. Emissions of NO_x have also decreased from the peak in 1975, with a 9–15% decrease from 1975 to 1988.

A commonly used indicator of the intensity of acid rain is the **pH** of this rainfall. The pH of non-polluted rainfall in forested regions is in the range 5.0–5.6. The upper limit is 5.6, not neutral (7.0), because of carbonic acid that results from the dissolution of atmospheric **carbon dioxide**. The contribution of naturally occurring nitric and sulfuric acid, as well as organic acids, reduces the pH somewhat to less than 5.6. In **arid** and semi-arid regions, rainfall pH values can be greater than 5.6 due the effect of alkaline **soil** dust in the air. Nitric and sulfuric acids in acidic rainfall (wet deposition) can result in pH values for individual rainfall events of less than 4.0.

In North America, the lowest acid rainfall is in the northeastern United States and southeastern Canada. The lowest mean pH in this region is 4.15. Even lower pH values

are observed in central and northern Europe. Generally, the greater the population density and density of industrialization the lower the rainfall pH. Long distance transport, however, can result in low pH rainfall even in areas with low population and low density of industries, as in parts of New England, eastern Canada, and in Scandinavia.

A very significant portion of acid deposition occurs in the dry form. In the United States, it is estimated that 30–60% of acidic deposition occurs as dry fall. This material is deposited as sulfur dioxide gas and very finely divided particles (aerosols) directly on the surfaces of plants (needles and leaves). The rate of deposition depends not only on the concentration of acid materials suspended in the air, but on the nature and density of plant surfaces exposed to the atmosphere and the atmospheric conditions(e.g., wind speed and humidity).

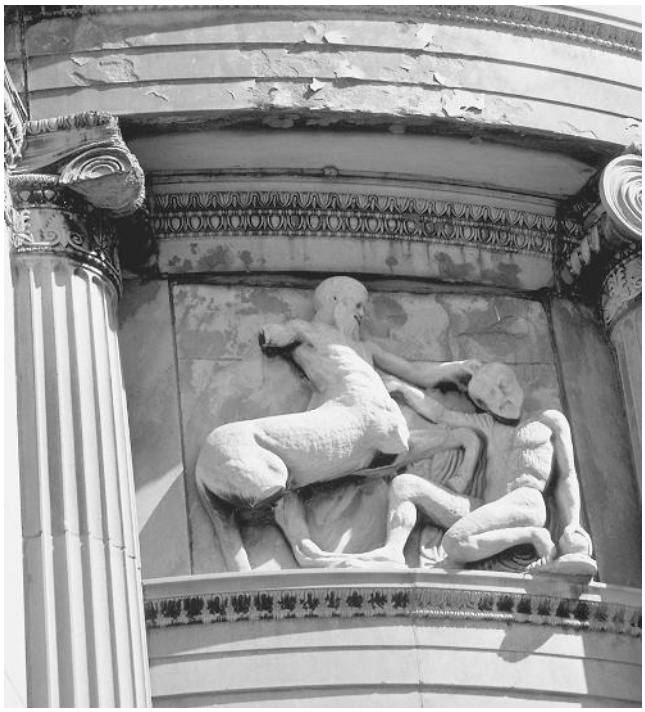
Direct deposition of acid cloud droplets can be very important especially in some high altitude forests. Acid cloud droplets can have acid concentrations of five to 20 times that in wet deposition. In some high elevation sites that are frequently shrouded in clouds, direct droplet deposition is three times that of wet deposition from rainfall.

Acid deposition has the potential to adversely affect sensitive forests as well as lakes and streams. Agriculture is generally not included in the assessment of the effects of acidic deposition because experimental evidence indicates that even the most severe episodes of acid deposition do not adversely affect the growth of agricultural crops, and any long-term soil **acidification** can readily be managed by addition of agricultural lime. In fact, the acidifying potential of the fertilizers normally added to cropland is much greater than that of acidic deposition. In forests, however, long-term acidic deposition on sensitive soils can result in the depletion of important **nutrient** elements (e.g., calcium, magnesium, and potassium) and in soil acidification. Also, acidic pollutants can interact with other pollutants (e.g., **ozone**) to cause more immediate problems for tree growth. Acid deposition can also result in the acidification of sensitive lakes and with the loss of biological productivity.

Long-term exposure of acid sensitive materials used in building construction and in monuments (e.g., zinc, marble, limestone, and some sandstone) can result in surface corrosion and deterioration. Monuments tend to be the most vulnerable because they are usually not as protected from rainfall as most building materials. Good data on the impact of acidic deposition on monuments and building material is lacking.

Nutrient depletion due to acid deposition on sensitive soils is a long-term (decades to centuries) consequence of acidic deposition. Acidic deposition greatly accelerates the very slow depletion of soil nutrients due to natural **weathering** processes. Soils that contain less plant-available calcium, magnesium and potassium are less buffered with respect to degradation due to acidic deposition. The most sensitive soils are shallow sandy soils over hard bedrock. The least vulnerable soils are the deep clay soils that are highly buffered against changes due to acidic deposition.

The more immediate possible threat to forests is the **forest decline** phenomenon that has been observed in forests in northern Europe and North America. Acidic deposition in combination with other stress factors such as ozone, disease and adverse weather conditions can lead to decline in forest productivity and, in certain cases, to **dieback**. Acid deposition alone cannot account for the observed forest decline, and acid deposition probably plays a minor role in the areas where forest decline has occurred. Ozone is a much more serious threat to forests, and it is a key factor in the decline of forests in the Sierra Nevada and San Bernardino mountains in California.



The greatest concern for adverse effects of acidic deposition is the decline in biological productivity in lakes. When a lake has a pH less than 6.0, several **species** of minnows, as well as other species that are part of the food chain for many fish, cannot survive. At pH values less than about 5.3, lake trout, walleye, and smallmouth bass cannot survive. At pH less than about 4.5, most fish cannot survive (largemouth bass are an exception).

Many small lakes are naturally acidic due to organic acids produced in acid soils and acid bogs. These lakes have chemistries dominated by organic acids, and many have brown colored waters due to the organic acid content. These lakes can be distinguished from lakes acidified by acidic deposition, because lakes strongly affected by acidic deposition are dominated by sulfate.

Lakes that are adversely affected by acidic deposition tend to be in steep terrain with thin soils. In these settings the path of rainwater movement into a lake is not influenced greatly by soil materials. This contrasts to most lakes where much of the water that collects in a lake flows first into the **groundwater** before entering the lake via subsurface flow. Due to the contact with soil materials, acidity is neutralized and the capacity to neutralize acidity is added to the water in the form of bicarbonate ions (bicarbonate alkalinity). If more than 5% of the water that reaches a lake is in the form of groundwater, a lake is not sensitive to acid deposition.

An estimated 24% of the lakes in the Adirondack region of New York are devoid of fish. In one third to one half of these lakes this is due to acidic deposition. Approximately 16% of the lakes in this region may have lost one or more species of fish due to acidification. In Ontario, Canada, 115 lakes are estimated to have lost populations of lake trout. Acidification of lakes, by acidic deposition, extends as far west as Upper Michigan and northeastern Wisconsin, where many sensitive lakes occur and there is some evidence for

Acid rain in Chicago, Illinois, erodes the structures of historical buildings. (Photograph by Richard P. Jacobs. JLM Visuals. Reproduced by permission.)

acidification. However, the extent of acidification is quite limited.

Acidification

The process of becoming more acidic due to inputs of an acidic substance. The common measure of acidification is a decrease in **pH**. Acidification of soils and natural waters by **acid rain** or **acid** wastes can result in reduced biological productivity if the pH is sufficiently reduced.

Activated sludge

The activated **sludge** process is an **aerobic** (oxygen-rich), continuous-flow biological method for the treatment of domestic and **biodegradable** industrial **wastewater**, in which organic matter is utilized by **microorganisms** for life-sustaining processes, that is, for energy for reproduction, digestion, movement, etc. and as a food source to produce cell growth and more microorganisms. During these activities of utilization and degradation of organic materials, degradation products of **carbon dioxide** and water are also formed. The activated sludge process is characterized by the suspension of microorganisms in the wastewater, a mixture referred to as the mixed liquor. Activated sludge is used as part of an overall treatment system, which includes primary treatment of the wastewater for the removal of **particulate** solids before the use of activated sludge as a secondary treatment process to remove suspended and dissolved organic solids.

The conventional activated sludge process consists of an **aeration** basin, with air as the oxygen source, where treatment is accomplished. Soluble (dissolved) organic materials are absorbed through the cell walls of the microorganisms and into the cells, where they are broken down and converted to more microorganisms, **carbon** dioxide, water, and energy. Insoluble (solid) particles are adsorbed on the cell walls, transformed to a soluble form by enzymes (biological catalysts) secreted by the microorganisms, and absorbed through the cell wall, where they are also digested and used by the microorganisms in their life-sustaining processes.

The microorganisms that are responsible for the degradation of the organic materials are maintained in suspension by mixing induced by the aeration system. As the microorganisms are mixed, they collide with other microorganisms and stick together to form larger particles called *floc*. The large flocs that are formed settle more readily than individual cells. These flocs also collide with suspended and colloidal materials (insoluble organic materials), which stick to the flocs and cause the flocs to grow even larger. The microor-

ganisms digest these adsorbed materials, thereby re-opening sites for more materials to stick.

The aeration basin is followed by a secondary clarifier (settling tank), where the flocs of microorganisms with their adsorbed organic materials settle out. A portion of the settled microorganisms, referred to as sludge, are recycled to the aeration basin to maintain an active population of microorganisms and an adequate supply of biological solids for the **adsorption** of organic materials. Excess sludge is wasted by being piped to separate sludge-handling processes. The liquids from the clarifier are transported to facilities for disinfection and final **discharge** to receiving waters, or to tertiary treatment units for further treatment.

Activated sludge processes are designed based on the mixed liquor suspended solids (MLSS) and the organic **loading** of the wastewater, as represented by the **biochemical oxygen demand** (BOD) or **chemical oxygen demand** (COD). The MLSS represents the quantity of microorganisms involved in the treatment of the organic materials in the aeration basin, while the organic loading determines the requirements for the design of the aeration system.

Modifications to the conventional activated sludge process include:

- *Extended aeration*. The mixed liquor is retained in the aeration basin until the production rate of new cells is the same as the decay rate of existing cells, with no excess sludge production. In practice, excess sludge is produced, but the quantity is less than that of other activated sludge processes. This process is often used for the treatment of industrial wastewater that contains complex organic materials requiring long detention times for degradation.
- *Contact stabilization*. A process based on the premise that as wastewater enters the aeration basin (referred to as the contact basin), colloidal and insoluble organic biodegradable materials are removed rapidly by biological **sorption**, synthesis, and flocculation during a relatively short contact time. This method uses a reaeration (stabilization) basin before the settled sludge from the clarifier is returned to the contact basin. The concentrated flocculated and adsorbed organic materials are oxidized in the reaeration basin, which does not receive any addition of raw wastewater.
- *Plug flow*. Wastewater is routed through a series of channels constructed in the aeration basin; wastewater flows through and is treated as a plug as it winds its way through the basin. As the "plug" passes through the tank, the concentrations of organic materials are gradually reduced, with a corresponding decrease in oxygen requirements and microorganism numbers.
- *Step aeration*. Influent wastewater enters the aeration basin along the length of the basin, while the return sludge enters at the head of the basin. This process results in a more uniform oxygen demand in the basin and a more stable **environment** for the microorganisms; it also results in a lower solids loading on the clarifier for a given mass of microorganisms.
- *Oxidation ditch*. A circular aeration basin (racetrack-shaped) is used, with rotary brush aerators that extend across the width of the ditch. Brush aerators aerate the wastewater, keep the microorganisms in suspension, and drive the wastewater around the circular channel.

Acute effects

Effects that persist in a biologic system for only a short time, generally less than a week. The effects might range from behavioral or color changes to death. Tests for acute effects are performed with humans, animals, plants, insects, and **microorganisms**. Intoxication and a hangover resulting from the consumption of too much alcohol, the common cold, and parathion **poisoning** are examples of acute effects. Generally, little tissue damage occurs as a result of acute effects. The term acute effects should not be confused with acute toxicity studies or acute dosages, which respectively refer to short-term studies (generally less than a week) and short-term dosages (often a single dose). Both chronic and acute exposures can initiate acute effects.

Ansel Easton Adams (1902 – 1984)

American photographer and conservationist

Ansel Adams is best known for his stark black-and-white photographs of **nature** and the American landscape. He was born and raised in San Francisco. Schooled at home by his parents, he received little formal training except as a pianist. A trip to Yosemite Valley as a teenager had a profound influence on him, and **Yosemite National Park** and the Sierra "range of light" attracted him back many times and inspired two great careers: photographer and conservationist. As he observed, "Everybody needs something to believe in [and] my point of focus is conservation." He used his photographs to make that point more vivid and turned it into an enduring legacy.

Adams was a painstaking artist, and some critics have chided him for an overemphasis on technique and for creating in his work "a mood that is relentlessly optimistic." Adams *was* a careful technician, making all of his own prints (reportedly hand-producing over 13,000 in his lifetime), sometimes spending a whole day on one print. He explained: "I have made thousands of photographs of the natural scene, but only those images that were most intensely felt at the moment of exposure have survived the inevitable winnowing of time."

He did winnow, ruthlessly, and the result was a collection of work that introduced millions of people to the majesty and diversity of the American landscape. Not all of Adams's pictures were "uplifting" or "optimistic" images of scenic wonders; he also documented scenes of **overgrazing** in the **arid** Southwest and of incarcerated Japanese-Americans in the Manzanar internment camp.

From the beginning, Adams used his photographs in the cause of **conservation**. His pictures played a major role in the late 1930s in establishing Kings Canyon National Park. Throughout his life, he remained an active, involved conservationist; for many years he was on the Board of the **Sierra Club** and strongly influenced the Club's activities and philosophy.

Ansel Adams's greatest bequest to the world will remain his photographs and advocacy of **wilderness** and the **national park** ideals. Through his work he not only generated interest in environmental conservation, he also captured the beauty and majesty of nature for all generations to enjoy.

Adaptation

All members of a population share many characteristics in common. For example, all finches in a particular forest are alike in many ways. But if many hard-to-shell seeds are found in the forest, those finches with stronger, more conical bills will have better rates of reproduction and survival than finches with thin bills. Therefore, a conical, stout bill can be considered an adaptation to that forest **environment**. Any specialized characteristic that permits an individual to survive and reproduce is called an adaptation. Adaptations may result either from an individual's genetic heritage or from its ability to learn. Since successful genetic adaptations are more likely to be passed from generation to generation through the survival of better adapted organisms, adaptation can be viewed as the force that drives biological **evolution**.

Adaptive management

Adaptive management is taking an idea, implementing it, and then documenting and learning from any mistakes or benefits of the experiment. The basic idea behind adaptive management is that natural systems are too complex, too non-linear, and too multi-scale to be predictable. Management policies and procedures must therefore become more adaptive and capable of change to cope with unpredictable systems.

Advocates suggest treating management policies as experiments, which are then designed to maximize learning rather than focusing on immediate resource yields. If the environmental and resource systems on which human beings depend are constantly changing, then societies who utilize that learning cannot rely on those systems to sustain continued use. Adaptive management mandates a continual experimental process, an on-going process of reevaluation and reassessment of planning methods and human actions, and a constant long-term monitoring of environmental impacts and change. This would keep up with the constant change in the environmental systems to which the policies or ideas are to be applied.

The Grand Canyon Protection Act of 1992 is one example of adaptive management at work. It entails the study and monitoring of the **Glen Canyon Dam** and the operational effects on the surrounding **environment**, both ecological and biological.

Haney and Power suggest that "uncertainty and complexity frustrate both science and management, and it is only by combining the best of both that we use all available tools to manage ecosystems sustainably." However, Fikret Berkes and colleagues claim that adaptive management can be attained by approaching it as a rediscovery of traditional ecological knowledge among **indigenous peoples**: "These traditional systems had certain similarities to adaptive management with its emphasis on feedback learning, and its treatment of uncertainty and unpredictability intrinsic to all ecosystems."

An editorial in the journal *Environment* offered the rather inane statement that adaptive management "has not realized its promise." The promise is in the idea, but implementation begins with people. Adaptive management, like **Smart Growth** and other seemingly innovative approaches

to **land use** and environmental management, is plagued by the problem of how to get people to actually put into practice what is proposed. Even for practical ideas the problem remains the same: not science, not technology, but human willfulness and human behavior. For policies or plans to be truly adaptive, the people themselves must be willing to adapt.

Haney and Power provide the conclusion: "When properly integrated, the [adaptive management] process is continuous and cyclic; components of the adaptive management model evolve as information is gained and social and ecological systems change. Unless management is flexible and innovative, outcomes become less sustainable and less accepted by stakeholders. Management will be successful in the face of complexity and uncertainty only with holistic approaches, good science, and critical evaluation of each step. Adaptive management is where it all comes together."

Adirondack Mountains

A range of mountains in northeastern New York, containing Mt. Marcy (5,344 ft; 1,644 m), the state's highest point. Bounded by the Mohawk Valley on the south, the St. Lawrence Valley on the northeast, and by the **Hudson River** and Lake Champlain on the east, the Adirondack Mountains form the core of Adirondack Park. This park is one of the earliest and most comprehensive examples of regional planning in the United States. The regional plan attempts to balance conflicting interests of many users at the same time as it controls environmentally destructive development. Although the plan remains controversial, it has succeeded in largely preserving one of the last and greatest **wilderness** areas in the East.

The Adirondacks serve a number of important purposes for surrounding populations. Vacationers, hikers, canoeists, and anglers use the area's 2,300 wilderness lakes and extensive river systems. The state's greatest remaining forests stand in the Adirondacks, providing animal **habitat** and serving recreational visitors. Timber and mining companies, employing much of the area's resident population, also rely on the forests, some of which contain the East's most ancient old-growth groves. Containing the headwaters of numerous rivers, including the Hudson, Adirondack Park is an essential source of clean water for farms and cities at lower elevations.

Adirondack Park was established by the New York State Constitution of 1892, which mandates that the region shall remain "forever wild." Encompassing six million acres (2.4 million ha), this park is the largest wilderness area in the eastern United States—nearly three times the size of **Yellowstone National Park**. Only a third of the land within park boundaries, however, is owned by the state of New York. Private mining and timber concerns, public agencies, several towns, thousands of private cabins, and 107 units of local government occupy the remaining property.

Because the development interests of various user groups and visitors conflict with the state constitution, a comprehensive regional **land use** plan was developed in 1972–1973. The novelty of the plan lay in the large area it covered and in its jurisdiction over land uses on private land as well as **public land**. According to the regional plan, all major development within park boundaries must meet an extensive set of environmental safeguards drawn up by the state's Adirondack Park Agency. Stringent rules and extensive regulation frustrate local residents and commercial interests, who complain about the plan's complexity and resent "outsiders" ruling on what Adirondackers are allowed to do. Nevertheless, this plan has been a milestone for other regions trying to balance the interests of multiple users. By controlling extensive development, the park agency has preserved a wilderness resource that has become extremely rare in the eastern United States. The survival of this century-old park, surrounded by extensive development, demonstrates the value of preserving wilderness in spite of ongoing controversy.

In recent years forestry and **recreation** interests in the Adirondacks have encountered a new environmental problem in **acid** precipitation. Evidence of deleterious effects of **acid rain** and snow on aquatic and terrestrial vegetation began to accumulate in the early 1970s. Studies revealed that about half of the Adirondack lakes situated above 3,300 ft (1,000 m) have **pH** levels so low that all fish have disappeared. Prevailing winds put these mountains directly downstream of urban and industrial regions of western New York

and southern Ontario. Because they form an elevated obstacle to weather patterns, these mountains capture a great deal of precipitation carrying acidic sulfur and **nitrogen oxides** from upwind industrial cities.

Adsorption

The removal of ions or molecules from solutions by binding to solid surfaces. **Phosphorus** is removed from water flowing through soils by adsorption on **soil** particles. Some pesticides adsorb strongly on soil particles. Adsorption by suspended solids is also an important process in natural waters.

AEC

see **Atomic Energy Commission**

AEM

see **Agricultural Environmental Management**

Aeration

In discussions of plant growth, aeration refers to an exchange that takes place in **soil** or another medium allowing oxygen to enter and **carbon dioxide** to escape into the **atmosphere**. Crop growth is often reduced when aeration is poor. In geology, particularly with reference to **groundwater**, aeration is the portion of the earth's crust where the pores are only partially filled with water. In relation to **water treatment**, aeration is the process of exposing water to air in order to remove such undesirable substances in drinking water as iron and manganese.

Aerobic

Refers to either an **environment** that contains molecular oxygen gas (O_2); an organism or tissue that requires oxygen for its **metabolism**; or a chemical or biological process that requires oxygen. Aerobic organisms use molecular oxygen in **respiration**, releasing **carbon dioxide** (CO_2) in return. These organisms include mammals, fish, birds, and green plants, as well as many of the lower life forms such as **fungi**, algae, and sundry bacteria and actinomycetes. Many, but not all, organic **decomposition** processes are aerobic; a lack of oxygen greatly slows these processes.

Aerobic/anaerobic systems

Most living organisms require oxygen to function normally, but a few forms of life exist exclusively in the absence of oxygen and some can function both in the presence of oxygen (aerobically) and in its absence (anaerobically). Examples of **anaerobic** organisms are found in bacteria of the genus *Clostridium*, in parasitic protozoans from the gastrointestinal tract of humans and other vertebrates, and in ciliates associated with sulfide-containing sediments. Organisms capable of switching between **aerobic** and anaerobic existence are found in forms of **fungi** known as yeasts. The ability of an organism to function both aerobically and anaerobically increases the variety of sites in which it is able to exist and conveys some advantages over organisms with less adaptive potential.

Microbial decay activity in **nature** can occur either aerobically or anaerobically. Aerobic **decomposers** of compost and other organic substrates are generally preferable because they act more quickly and release fewer noxious odors. Large **sewage treatment** plants use a two-stage digestion system in which the first stage is **anaerobic digestion** of **sludge** that produces flammable **methane** gas that may be used as fuel to help operate the plant. Sludge digestion continues in the aerobic second stage, a process which is easier to control but more costly because of the power needed to provide **aeration**. Although most fungi are generally aerobic organisms, yeasts used in bread making and in the production of fermented beverages such as wine and beer can metabolize anaerobically. In the process, they release ethyl alcohol and the **carbon dioxide** that causes bread to rise.

Tissues of higher organisms may have limited capability for anaerobic **metabolism**, but they need elaborate compensating mechanisms to survive even brief periods without oxygen. For example, human muscle tissue is able to metabolize anaerobically when blood cannot supply the large amounts of oxygen needed for vigorous activity. Muscle contraction requires an energy-rich compound called adeno-

sine triphosphate (ATP). Muscle tissue normally contains enough ATP for 20–30 seconds of intense activity. ATP must then be metabolically regenerated from glycogen, the muscle's primary energy source. Muscle tissue has both aerobic and anaerobic metabolic systems for regenerating ATP from glycogen. Although the aerobic system is much more efficient, the anaerobic system is the major energy source for the first minute or two of exercise. The **carbon** dioxide released in this process causes the heart rate to increase. As the heart beats faster and more oxygen is delivered to the muscle tissue, the more efficient aerobic system for generating ATP takes over. A person's physical condition is important in determining how well the aerobic system is able to meet the needs of continued activity. In fit individuals who exercise regularly, heart function is optimized, and the heart is able to pump blood rapidly enough to maintain aerobic metabolism. If the oxygen level in muscle tissue drops, anaerobic metabolism will resume. Toxic products of anaerobic metabolism, including lactic **acid**, accumulate in the tissue, and muscle fatigue results.

Other interesting examples of limited anaerobic capability are found in the animal kingdom. Some diving ducks have an **adaptation** that allows them to draw oxygen from stored oxyhemoglobin and oxymyoglobin in blood and muscles. This adaptation permits them to remain submerged in water for extended periods. To prevent desiccation, mussels and clams close their shells when out of the water at low tide, and their metabolism shifts from aerobic to anaerobic. When once again in the water, the animals rapidly return to aerobic metabolism and purge themselves of the acid products of anaerobiosis accumulated while they were dry.

Aerobic sludge digestion

Wastewater treatment plants produce organic **sludge** as wastewater is treated; this sludge must be further treated before ultimate disposal. Sludges are generated from primary settling tanks, which are used to remove settable, **particulate** solids, and from secondary clarifiers (settling basins), which are used to remove excess **biomass** production generated in secondary biological treatment units.

Disposal of sludges from wastewater treatment processes is a costly and difficult problem. The processes used in sludge disposal include: (1) reduction in sludge volume, primarily by removal of water, which constitutes 97–98% of the sludge; (2) reduction of the volatile (organic) content of the sludge, which eliminates nuisance conditions by reducing putrescibility and reduces threats to human health by reducing levels of **microorganisms**; and (3) ultimate disposal of the residues.

Aerobic sludge digestion is one process that may be used to reduce both the organic content and the volume of the sludge. Under aerobic conditions, a large portion of the organic matter in sludge may be oxidized biologically by microorganisms to **carbon dioxide** and water. The process results in approximately 50% reduction in solids content. Aerobic sludge digestion facilities may be designed for batch or continuous flow operations. In batch operations, sludge is added to a reaction tank while the contents are continuously aerated. Once the tank is filled, the sludges are aerated for two to three weeks, depending on the types of sludge. After **aeration** is discontinued, the solids and liquids are separated. Solids at concentrations of 2–45 are removed, and the clarified liquid supernatant is decanted and recycled to the wastewater treatment plant. In a continuous flow system, an aeration tank is utilized, followed by a settling tank.

Aerobic sludge digestion is usually used only for biological sludges from secondary treatment units, in the absence of sludges from primary treatment units. The most commonly used application is for the treatment of sludges wasted from extended aeration systems (which is a modification of the **activated sludge** system). Since there is no addition of an external food source, the microorganisms must utilize their own cell contents for metabolic purposes in a process called endogenous **respiration**. The remaining sludge is a mineralized sludge, with remaining organic materials comprised of cell walls and other cell fragments that are not readily **biodegradable**.

The advantages of using aerobic digestion, as compared to the use of **anaerobic digestion** include: (1) simplicity of operation and maintenance; (2) lower capital costs; (3) lower levels of **biochemical oxygen demand** (BOD) and **phosphorus** in the supernatant; (4) fewer effects from upsets such as the presence of toxic interferences or changes in **loading** and **pH**; (5) less odor; (6) nonexplosive; (7) greater reduction in grease and hexane solubles; (8) greater sludge **fertilizer** value; (9) shorter retention periods; and (10) an effective alternative for small wastewater treatment plants.

Disadvantages include: (1) higher operating costs, especially energy costs; (2) highly sensitive to ambient temperature (operation at temperatures below 59°F [15°C]) may require excessive retention times to achieve stabilization; if heating is required, aerobic digestion may not be cost-effective); (3) no useful byproduct such as **methane** gas that is produced in **anaerobic** digestion; (4) variability in the ability to dewater to reduce sludge volume; (5) less reduction in volatile solids; and (6) unfavorable economics for larger wastewater treatment plants.

Aerosol

A suspension of particles, liquid or solid, in a gas. The term implies a degree of permanence in the suspension, which puts a rough upper limit on particle size at a few tens of micrometers at most (1 micrometer = 0.00004 in). Thus in proper use the term connotes the ensemble of the particles and the suspending gas.

The atmospheric aerosol has two major components, generally referred to as coarse and fine particles, with different sources and different composition. Coarse particles result from mechanical processes, such as grinding. The smaller particles are ground, the more surface they have per unit of mass. Creating new surface requires energy, so the smallest average size that can be created by such processes is limited by the available energy. It is rare for such mechanically generated particles to be less than 1 μm (0.00004 in.) in diameter. Fine particles, on the other hand, are formed by condensation from the vapor phase. For most substances, condensation is difficult from a uniform gaseous state; it requires the presence of pre-existing particles on which the vapors can deposit. Alternatively, very high concentrations of the vapor are required, compared with the concentration in equilibrium with the condensed material.

Hence, fine particles form readily in **combustion** processes when substances are vaporized. The gas is then quickly cooled. These can then serve as nuclei for the formation of larger particles, still in the fine particle size range, in the presence of condensable vapors. However, in the **atmosphere** such particles become rapidly more scarce with increasing size, and are relatively rare in sizes much larger than a few micrometers. At about 2 μm (0.00008 in.), coarse and fine particles are about equally abundant.

Using the term strictly, one rarely samples the atmospheric aerosol, but rather the particles out of the aerosol. The presence of aerosols is generally detected by their effect on light. Aerosols of a uniform particle size in the vicinity of the wavelengths of visible light can produce rather spectacular optical effects. In the laboratory, such aerosols can be produced by condensation of the heated vapors of certain oils on nuclei made by evaporating salts from heated filaments. If the suspending gas is cooled quickly, particle size is governed by the supply of vapor compared with the supply of nuclei, and the time available for condensation to occur. Since these can all be made nearly constant throughout the gas, the resulting particles are quite uniform. It is also possible to produce uniform particles by spraying a dilute solution of a soluble material, then evaporating the solvent. If the spray head is vibrated in an appropriate frequency range, the drops will be uniform in size, with the size controlled by the frequency of vibration and the rate of flow of the spray. Obviously, the final particle size is also a function of the concentration of the sprayed solution.

Aflatoxin

Toxic compounds produced by some **fungi** and among the most potent naturally occurring carcinogens for humans and animals. Aflatoxin intake is positively related to high incidence of liver **cancer** in humans in many developing countries. In many farm animals aflatoxin can cause acute or chronic diseases. Aflatoxin is a metabolic by-product produced by the fungi *Aspergillus flavus* and the closely related **species** *Aspergillus parasiticus* growing on grains and decaying organic compounds. There are four naturally occurring aflatoxins: B_1, B_2, G_1, and G_2. All of these compounds will fluoresce under a UV (black) light around 425–450 nm providing a qualitative test for the presence of afla-

toxins. In general, starch grains, such as corn, are infected in storage when the moisture content of the grain reaches 17–18% and the temperature is 79–99°F (26–37°C). However, the fungus may also infect grain in the field under hot, dry conditions.

African Wildlife Foundation

The African Wildlife Foundation (AWF), headquartered in Washington, DC, was established in 1961 to promote the protection of the animals native to Africa. The group maintains offices in both Washington, DC, and Nairobi, Kenya. The African headquarters promotes the idea that Africans themselves are best able to protect the wildlife of their continent. AWF also established two colleges of **wildlife management** in Africa (Tanzania and Cameroon), so that rangers and park and reserve wardens can be professionally trained. **Conservation** education, especially as it relates to African wildlife, has always been a major AWF goal—in fact, it has been the association's primary focus since its inception.

AWF carries out its mandate to protect Africa's wildlife through a wide range of projects and activities. Since 1961, AWF has provided a radio communication network in Africa, as well as several airplanes and jeeps for antipoaching patrols. These were instrumental in facilitating the work of Dr. **Richard Leakey** in the Tsavo National Park, Kenya. In 1999, the African Hearlands project was set up and to try to connect large areas of wild land which is home to wild animals. They also attempt to involve people who live adjacent to protected wildlife areas by asking them to take joint responsibility for **natural resources**. The program demonstrates that land conservation and the needs of neighboring people and their livestock can be balanced, and the benefits shared. Currently there are four heartland areas: Maasai Steppe, Kilimanjaro, Virunga, and Samburu.

Another highly successful AWF program is the Elephant Awareness Campaign. Its slogan, "Only **Elephants** Should Wear Ivory," has become extremely popular, both in Africa and in the United States, and is largely responsible for bringing the plight of the African elephant (*Loxodonta africana*) to public awareness.

Although AWF is concerned with all the wildlife of Africa, in recent years the group has focused on saving African elephants, black **rhinoceroses** (*Diceros bicornis*), and mountain gorillas (*Gorilla gorilla berengei*). These **species** are seriously endangered, and are benefiting from AWF's Critical Habitats and Species Program, which works to aid these and other animals in critical danger.

From its inception, AWF has supported education centers, wildlife clubs, **national parks**, and reserves. There is even a course at the College of African Wildlife Management in Tanzania that allows students to learn community conservation activities and helps park officials learn to work with residents living adjacent to protected areas. AWF also involves teachers in its endeavors with a series of publications, *Let's Conserve Our Wildlife*. Written in Swahili, the series includes teacher's guides and has been used in both elementary schools and adult literacy classes in African villages. AWF also publishes the quarterly magazine *Wildlife News*.

Africanized bees

The Africanized bee (*Apis mellifera scutellata*), or "killer bee," is an extremely aggressive honeybee. This bee developed when African honeybees were brought to Brazil to mate with other bees to increase honey production. The imported bees were accidentally released and they have since spread northward, traveling at a rate of 300 mi (483 km) per year. The bees first appeared in the United States at the Texas-Mexico border in late 1990.

The bees get their "killer" title because of their vigorous defense of colonies or hives when disturbed. Aside from temperament, they are much like their counterparts now in the United States, which are European in lineage. Africanized bees are slightly smaller than their more passive cousins.

Honeybees are social insects and live and work together in colonies. When bees fly from plant to plant, they help pollinate flowers and crops. Africanized bees, however, seem to be more interested in reproducing than in honey production or **pollination**. For this reason they are constantly swarming and moving around, while domestic bees tend to stay in local, managed colonies. Because Africanized bees are also much more aggressive than domestic honey bees when their colonies are disturbed, they can be harmful to people who are allergic to bee stings.

More problematic than the threat to humans, however, is the impact the bees will have on fruit and vegetable industries in the southern parts of the United States. Many fruit and vegetable growers depend on honey bees for pollination, and in places where the Africanized bees have appeared, honey production has fallen by as much as 80%. Beekeepers in this country are experimenting with "re-queening" their

An Africanized bee collecting grass pollen in Brazil. (Photograph by Scott Camazine. Photo Researchers Inc. Reproduced by permission.)

colonies regularly to ensure that the colonies reproduce gentle offspring.

Another danger is the propensity of the Africanized bee to mate with honey bees of European lineage, a kind of "infiltration" of the **gene pool** of more domestic bees. Researchers from the **U.S. Department of Agriculture** (USDA) are watching for the results of this interbreeding, particularly for those bees that display European-style physiques and African behaviors, or vice versa.

When Africanized bees first appeared in southern Texas, researchers from the USDA's Honeybee Research Laboratory in Weslaco, Texas, destroyed the colony, estimated at 5,000 bees. Some of the members of the 3-lb (1.4 kg) colony were preserved in alcohol and others in freezers for future analysis. Researchers are also developing management techniques, including the annual introduction of young mated European queens into domestic hives, in an attempt to maintain gentle production stock and ensure honey production and pollination.

As of 2002, there were 140 counties in Texas, nine in New Mexico, nine in California, three in Nevada, and all of the 15 counties in Arizona in which Africanized bee colonies had been located. There have also been reported colonies in Puerto Rico and the Virgin Islands. Southern Nevada bees were almost 90% Africanized in June of 2001. Most of Texas has been labeled as a quarantine zone, and beekeepers are not able to move hives out of these boundaries. The largest colony found to date was in southern Phoenix, Arizona. The hive was almost 6 ft (1.8 m) long and held about 50,000 Africanized bees.

Agency for Toxic Substances and Disease Registry

The Agency for Toxic Substances and Disease Registry (ATSDR) studies the health effects of hazardous substances in general and at specific locations. As indicated by its title, the Agency maintains a registry of people exposed to toxic **chemicals**. Along with the **Environmental Protection Agency** (EPA), ATSDR prepares and updates profiles of toxic substances. In addition, ATSDR assesses the potential dangers posed to human health by exposure to hazardous substances at Superfund sites. The Agency will also perform health assessments when petitioned by a community. Though ATSDR's early health assessments have been criticized, the Agency's later assessments and other products are considered more useful.

ATSDR was created in 1980 by the **Comprehensive Environmental Response, Compensation, and Liability Act** (CERCLA), also known as the Superfund, as part of the **U.S. Department of Health and Human Services**. As originally conceived, ATSDR's role was limited to performing health studies and examining the relationship between toxic substances and disease. The Superfund Amendments and Reauthorization Act (SARA) of 1986 codified ATSDR's responsibility for assessing health threats at Superfund sites. ATSDR, along with the national Centers for Disease Control and state health departments, conducts health surveys in communities near locations that have been

placed on the Superfund's **National Priorities List** for clean up. ATSDR has preformed 951 health assessments in the two years after the law was passed. Approximately one quarter of these assessments were memos or reports that had been completed prior to 1986 and were simply re-labeled as health assessments.

These first assessments have been harshly criticized. The General Accounting Office (GAO), a congressional agency that reviews the actions of the federal administration, charged that most of these assessments were inadequate. Some argued that the agency was underfunded and poorly organized. Recently, ATSDR received less than 5% of the $1.6 billion appropriated for the Superfund project.

Subsequent health assessments, more than 200 of them, have generally been more complete, but they still may not be adequate in informing the community and the EPA of the dangers at specific sites. In general, ATSDR identifies a local agency to help prepare the health surveys. Unlike many of the first assessments, more recent surveys now include site visits and face-to-face interviews. However, other data on environmental effects are limited. ATSDR only considers environmental information provided by the companies that created the hazard or data collected by the EPA. In addition, ATSDR only assesses health risks from illegal emissions, not from "permitted" emissions. Some scientists contend that not enough is known about the health effects of exposure to hazardous substances to make conclusive health assessments.

Reaction to the performance of ATSDR's other functions has been generally more positive. As mandated by SARA, ATSDR and the EPA have prepared hundreds of toxicological profiles of hazardous substances. These profiles have been judged generally helpful, and the GAO praised ATSDR's registry of people who have been exposed to toxic substances.

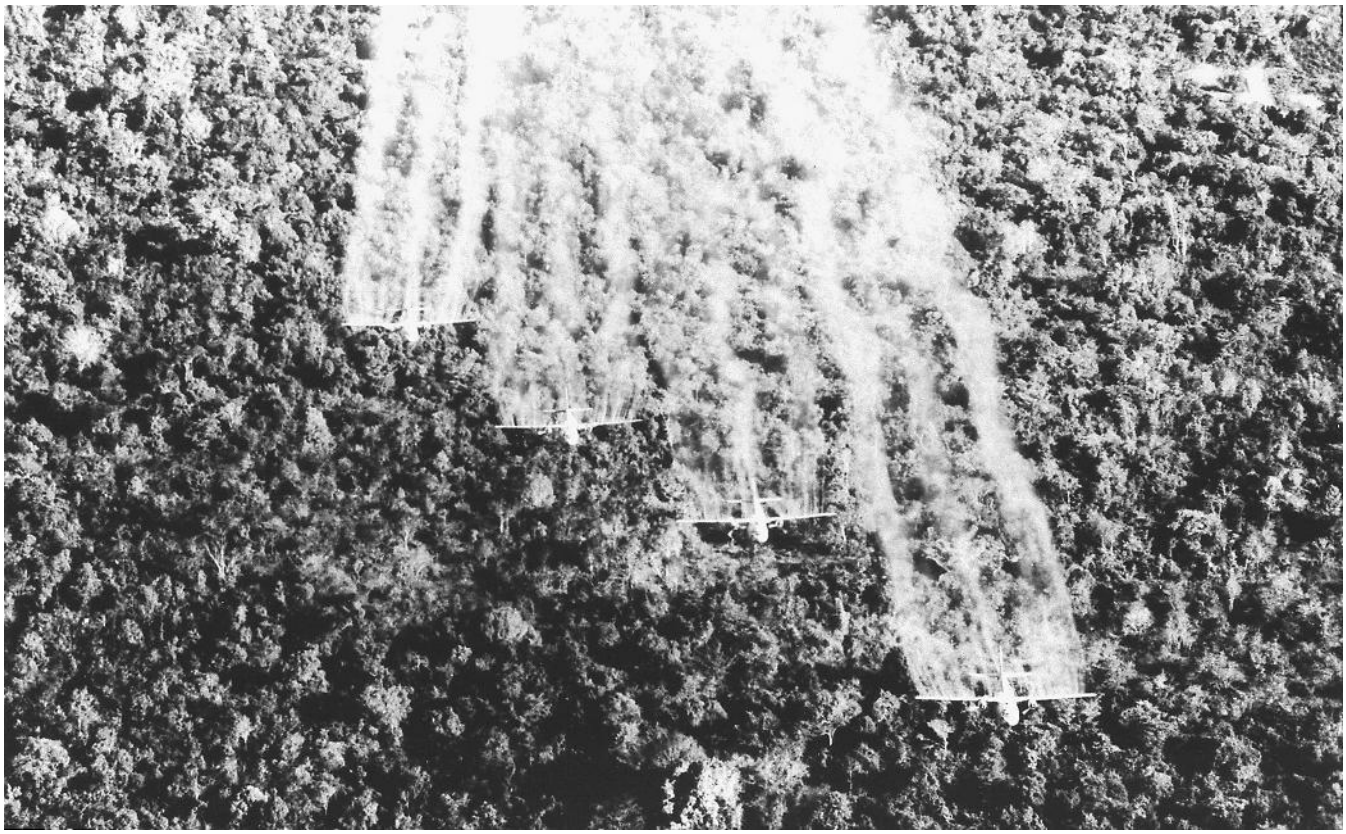
Agent Orange



Agent Orange is a **herbicide** recognized for its use during the Vietnam War. It is composed of equal parts of two **chemicals**: **2,4-D** and **2,4,5-T**. A less potent form of the herbicide has also been used for clearing heavy growth on a commercial basis for a number of years. However, it does not contain 2,4-D. On a commercial level, the herbicide was used in forestry control as early as the 1930s. In the 1950s through the 1960s, Agent Orange was also exported. For example, New Brunswick, Canada, was the scene of major Agent Orange spraying to control forests for industrial development. In Malaysia in the 1950s, the British used compounds with the chemical mixture 2,4,5-T to clear communication routes.

In the United States, herbicides were considered for military use towards the end of World War II, during the action in the Pacific. However, the first American military field tests were actually conducted in Puerto Rico, Texas, and Fort Drum, New York, in 1959.

That same year—1959—the Crops Division at Fort Detrick, Maryland initiated the first large-scale military **defoliation** effort. The project involved the aerial application of Agent Orange to about 4 mi^2 (10.4 km^2) of vegetation. The experiment proved highly successful; the military had found an effective tool. By 1960, the South Vietnamese government, aware of these early experiments, had requested that the United States conduct trials of these herbicides for use against guerrilla forces. Spraying of Agent Orange in Southeast Asia began in 1961. South Vietnam President Diem stated that he wanted this "powder" in order to destroy the rice and the food crops that would be used by the Viet Cong. Thus began the use of herbicides as a weapon of war.

The United States military became involved, recognizing the limitations of fighting in foreign territory with troops that were not accustomed to jungle conditions. The military wanted to clear communication lines and open up areas of **visibility** in order to enhance their opportunities for success. Eventually, the United States military took complete control of the spray missions. Initially, there were to be restrictions: the spraying was to be limited to clearing power lines and roadsides, railroads and other lines of communications and areas adjacent to depots. Eventually, the spraying was used to defoliate the thick jungle brush, thereby obliterating enemy hiding places.

Once under the authority of the military, and with no checks or restraints, the spraying continued to increase in

Deforestation of the Viet Cong jungle in South Vietnam. (AP/Wide World Photos. Reproduced by permission.)

intensity and abandon, escalating in scope because of military pressure. It was eventually used to destroy crops, mainly rice, in an effort to deprive the enemy of food. Unfortunately, the civilian population—Vietnamese men, women, and children—was also affected. The United States military sprayed 3.6 million acres (1.5 million ha) with 19 million gal (720 million l) of Agent Orange over nine years.

The spraying also became useful in clearing military base perimeters, cache sites, and waterways. Base perimeters were often sprayed more than once. In the case of dense jungle growth, one application of spray was made for the upper and another for the lower layers of vegetation. Inland forests, mangrove forests, and cultivated lands were all targets. Through Project Ranch Hand—the Air Force team assigned to the spray missions—Agent Orange became the most widely produced and dispensed defoliant in Vietnam.

Military requirements for herbicide use were developed by the Army's Chemical Operations Division, J-3, Military Assistance Command, Vietnam, (MACV). With Project Ranch Hand underway, the spray missions increased monthly after 1962. This increase was made possible by the continued military promises to stay away from the civilians or to re-settle those civilians and re-supply the food in any areas where herbicides destroyed the food of the innocent. These promises were never kept. The use of herbicides for crop destruction peaked in 1965 when 45% of the total spraying was designed to destroy crops.

Initially, the aerial spraying took place near Saigon. Eventually the geographical base was widened. During the 1967 expansion period of herbicide procurement, when requirements had become greater than the industries' ability to produce, the Air Force and Joint Chiefs of Staff become actively involved in the herbicide program. All production for commercial use was diverted to the military, and the Department of Defense (DOD) was appointed to deal with problems of procurement and production. Commercial producers were encouraged to expand their facilities and build new plants, and the DOD made attractive offers to companies that might be induced to manufacture herbicides. A number of companies were awarded contracts. Working closely with the military, certain chemical companies sent technical advisors to Vietnam to instruct personnel on the methods and techniques necessary for effective use of the herbicides.

During the peak of the spraying, approximately 129 sorties were flown per aircraft. Twenty-four UC-123B aircraft were used, averaging 39 sorties per day. In addition, there were trucks and helicopters that went on spraying missions, backed up by such countries as **Australia**. C-123 cargo planes and helicopters were also used. Helicopters flew without cargo doors so that frequent ground fire could be returned. But the rotary blades would kick up gusts of spray, thereby delivering a powerful dose onto the faces and bodies of the men inside the plane.

The dense Vietnamese jungle growth required two applications to defoliate both upper and lower layers of vegetation. On the ground, both enemy troops and Vietnamese civilians came in contact with the defoliant. American troops were also exposed. They could inhale the fine misty spray or be splashed in the sudden and unexpected deluge of an emergency dumping. Readily absorbing the chemicals through their skin and lungs, hundreds of thousands of United States military troops were exposed as they lived on the sprayed bases, slept near empty drums, and drank and washed in water in areas where defoliation had occurred. They ate food that had been brushed with spray. Empty herbicide drums were indiscriminately used and improperly stored. Volatile fumes from these drums caused damage to shade trees and to anyone near the fumes. Those handling the herbicides in support of a particular project goal had the unfortunate opportunity of becoming directly exposed on a consistent basis. Nearly three million veterans served in Southeast Asia. There is growing speculation that nearly everyone who was in Vietnam was eventually exposed to some degree—far less a possibility for those stationed in urban centers or on the waters.

According to official sources, in addition to the Ranch Hand group at least three groups were exposed:

- A group considered secondary support personnel. This included Army pilots who may have been involved in helicopter spraying, along with the Navy and Marine pilots.
- Those who transported the herbicide to Saigon, and from there to Bien Hoa and Da Nang. Such personnel transported the herbicide in the omnipresent 55-gallon (208-l) containers.
- Specialized mechanics, electricians, and technical personnel assigned to work on various aircraft. Many of this group were not specifically assigned to Ranch Hand but had to work in aircraft that were repeatedly contaminated.

Agent Orange was used in Vietnam in undiluted form at the rate of 3–4 gal (11.4-15.2 l) per acre. 13.8 lb (6.27 kg) of the chemical 2,4,5-T were added to 12 lb (5.5 kg) of 2,4-D per acre, a nearly 50-50 ratio. This intensity is 13.3 lb (6.06 kg) per acre more than was recommended by the military's own manual. Computer tapes (HERBS TAPES) now available show that some areas were sprayed as much as 25 times in just a few short months, thereby dramatically increasing the exposure to anyone within those sprayed areas. Between 1962 and 1971 an estimated 11.2 million gal (42.4 million l) of Agent Orange were dumped over South Vietnam.

Evaluations show that the chemical had killed and defoliated 90–95% of the treated vegetation. Thirty-six percent of all mangrove forest areas in South Vietnam were destroyed. Viet Cong tunnel openings, caves, and above ground shelters were revealed to the aircraft after the herbicides were shipped in drums identified by an orange stripe and a contract identification number that enabled the government to identify the specific manufacturer. The drums were sent to a number of central **transportation** points for shipment to Vietnam.

Agent Orange is contaminated by the chemical **dioxin**, specifically TCDD. In Vietnam, the dioxin concentration in Agent Orange varied from **parts per billion** (ppb) to **parts per million** (ppm), depending on each manufacturer's production methods. The highest reported concentration in Agent Orange was 45 ppm. The **Environmental Protection Agency** (EPA) evacuated **Times Beach**, Missouri, when tests revealed **soil** samples there with two parts per billion of dioxin. The EPA has stated that one ppb is dangerous to humans.

Ten years after the spraying ended, the agricultural areas remained barren. Damaging amounts of dioxin stayed in the soil thus infecting the food chain and exposing the Vietnamese people. As a result there is some concern that the high levels of TCDD are responsible for infant **mortality**, **birth defects**, and spontaneous abortions that occur in higher numbers in the once sprayed areas of Vietnam. Another report indicates that thirty years after Agent Orange contaminated the area, there is 100 times as much dioxin found in the bloodstream of people living in the area than those living in non-contaminated areas of Vietnam. This is a result of the dioxin found in the soil of the once heavily sprayed land. The chemical is then passed on to humans through the food they eat. Consequently, dioxin is also spread to infants through the mother's breast milk, which will undoubtedly affect the child's development.

In 1991 Congress passed the Agent Orange Act(-Public Law 102-4), which funded the extensive scientific study of the long-term health effects of Agent Orange and other herbicides used in Vietnam. As of early 2002, Agent Orange had been linked to the development of peripheral neuropathy, type II diabetes, prostate **cancer**, multiple myeloma, lymphomas, soft tissue sarcomas, and respiratory cancers. Researchers have also found a possible correlation between dioxin and the development of spinal bifida, a birth defect, and childhood **leukemia** in offspring of exposed vets. It is important to acknowledge the **statistics** do not

necessarily show a strong link between exposure to Agent Orange or TCDD and some of the conditions listed above. However, Vietnam veterans who were honorably discharged and have any of these "presumptive" conditions (i.e., conditions presumed caused by wartime exposure) are entitled to Veterans Administration (VA) health care benefits and disability compensation under federal law. Unfortunately many Vietnamese civilians will not receive any benefits despite the evidence that they continue to suffer from the affects of Agent Orange.

Agglomeration

Any process by which a group of individual particles is clumped together into a single mass. The term has a number of specialized uses. Some types of rocks are formed by the agglomeration of particles of sand, clay, or some other material. In geology, an agglomerate is a rock composed of volcanic fragments. One technique for dealing with **air pollution** is ultrasonic agglomeration. A source of very high frequency sound is attached to a smokestack, and the ultrasound produced by this source causes tiny **particulate** matter in waste gases to agglomerate into particles large enough to be collected.

Agricultural chemicals

The term agricultural chemical refers to any substance involved in the growth or utilization of any plant or animal of economic importance to humans. An agricultural chemical may be a natural product, such as urea, or a synthetic chemical, such as DDT. The agricultural **chemicals** now in use include fertilizers, pesticides, growth regulators, animal feed supplements, and raw materials for use in chemical processes.

In the broadest sense, agricultural chemicals can be divided into two large categories, those that promote the growth of a plant or animal and those that protect plants or animals. To the first group belong plant fertilizers and animal food supplements, and to the latter group belong pesticides, herbicides, animal vaccines, and antibiotics.

In order to stay healthy and grow normally, crops require a number of nutrients, some in relatively large quantities called macronutrients, and others in relatively small quantities called micronutrients. **Nitrogen**, **phosphorus**, and potassium are considered macronutrients, and boron, calcium, **chlorine**, **copper**, iron, magnesium, manganese among others are micronutrients.

Farmers have long understood the importance of replenishing the **soil**, and they have traditionally done so by natural means, using such materials as manure, dead fish, or compost. Synthetic fertilizers were first available in the early twentieth century, but they became widely used only after World War II. By 1990 farmers in the United States were using about 20 million tons (20.4 million metric tons) of these fertilizers a year.

Synthetic fertilizers are designed to provide either a single **nutrient** or some combination of nutrients. Examples of single-component or "straight" fertilizers are urea (NH_2CONH_2), which supplies nitrogen, or potassium chloride (KCl), which supplies potassium. The composition of "mixed" fertilizers, those containing more than one nutrient, is indicated by the analysis printed on their container. An 8-10-12 **fertilizer**, for example, contains 8% nitrogen by weight, 10% phosphorus, and 12% potassium.

Synthetic fertilizers can be designed to release nutrients almost immediately ("quick-acting") or over longer periods of time ("time-release"). They may also contain specific amounts of one or more trace nutrients needed for particular types of crops or soil. Controlling micronutrients is one of the most important problems in fertilizer compounding and use; the presence of low concentrations of some elements can be critical to a plant's health, while higher levels can be toxic to the same plants or to animals that ingest the micronutrient.

Plant growth patterns can also be influenced by direct application of certain chemicals. For example, the gibberellins are a class of compounds that can dramatically affect the rate at which plants grow and fruits and vegetables ripen. They have been used for a variety of purposes ranging from the hastening of root development to the delay of fruit ripening. Delaying ripening is most important for marketing agricultural products because it extends the time a crop can be transported and stored on grocery shelves. Other kinds of chemicals used in the processing, transporting, and storage

of fruits and vegetables include those that slow down or speed up ripening (maleic hydrazide, ethylene oxide, potassium permanganate, ethylene, and acetylene are examples), that reduce weight loss (chlorophenoxyacetic **acid**, for example), retain green color (cycloheximide), and control firmness (ethylene oxide).

The term agricultural chemical is most likely to bring to mind the range of chemicals used to protect plants against competing organisms: pesticides and herbicides. These chemicals disable or kill bacteria, **fungi**, rodents, worms, snails and slugs, insects, mites, algae, termites, or any other **species** of plant or animal that feeds upon, competes with, or otherwise interferes with the growth of crops. Such chemicals are named according to the organism against which they are designed to act. Some examples are fungicides (designed to kill fungi), insecticides (used against insects), nematicides (to kill round worms), avicides (to control birds), and herbicides (to combat plants). In 1990, 393 million tons of herbicides, 64 million tons of insecticides, and 8 million tons of other pesticides were used on American farmlands.

The introduction of synthetic pesticides in the years following World War II produced spectacular benefits for farmers. More than 50 major new products appeared between 1947 and 1967, resulting in yield increases in the United States ranging from 400% for corn to 150% for sorghum and 100% for wheat and soybeans. Similar increases in **less developed countries**, resulting from the use of both synthetic fertilizers and pesticides, eventually became known as the Green Revolution.

By the 1970s, however, the environmental consequences of using synthetic pesticides became obvious. Chemicals were becoming less effective as pests developed resistances to them, and their toxic effects on other organisms had grown more apparent. Farmers were also discovering drawbacks to chemical fertilizers as they found that they had to use larger and larger quantities each year in order to maintain crop yields. One solution to the environmental hazards posed by synthetic pesticides is the use of natural chemicals such as juvenile hormones, sex attractants, and anti-feedant compounds. The development of such natural pest-control materials has, however, been relatively modest; the vast majority of agricultural companies and individual farmers continue to use synthetic chemicals that have served them so well for over a half century.

Chemicals are also used to maintain and protect livestock. At one time, farm animals were fed almost exclusively on readily available natural foods. They grazed on **rangelands** or were fed hay or other grasses. Today, carefully blended chemical supplements are commonly added to the diet of most farm animals. These supplements have been determined on the basis of extensive studies of the nutrients that contribute to the growth or milk production of cows, sheep, goats, and other types of livestock. A typical animal supplement diet consists of various vitamins, minerals, amino acids, and nonprotein (simple) nitrogen compounds. The precise formulation depends primarily on the species; a vitamin supplement for cattle, for example, tends to include A, D, and E, while swine and poultry diets would also contain Vitamin K, riboflavin, niacin, pantothenic acid, and choline.

A number of chemicals added to animal feed serve no nutritional purpose but provide other benefits. For example, the addition of certain hormones to the feed of dairy cows can significantly increase their output of milk. **Genetic engineering** is also becoming increasingly important in the modification of crops and livestock. Cows injected with a genetically modified chemical, bovine somatotropin, produce a significantly larger quantity of milk.

It is estimated that infectious diseases cause the death of 15–20 of all farm animals each year. Just as plants are protected from pests by pesticides, so livestock are protected from disease organisms by immunization, antibiotics, and other techniques. Animals are vaccinated against species-specific diseases, and farmers administer antibiotics, sulfonamides, nitrofurans, arsenicals, and other chemicals that protect against disease-causing organisms.

The use of chemicals with livestock can have deleterious effects, just as crop chemicals have. In the 1960s, for example, the hormone diethylstilbestrol (DES) was widely used to stimulate the growth of cattle, but scientists found that detectable residues of the hormone remained in meat sold from the slaughtered animals. DES is now considered a **carcinogen**, and the U.S. **Food and Drug Administration** has banned its use in cattle feed since 1979.

Agricultural environmental management

The complex interaction of agriculture and **environment** has been an issue since the beginning of man. Humans grow

food to eat and also hunt animals that depend on natural resources for healthy ongoing habitats. Therefore, the world's human population must balance farming activities with maintaining natural resources. The term agriculture originally meant the act of cultivating fields or growing crops. However, it has expanded to include raising livestock as well.

When early settlers began farming and ranching in the United States, they faced pristine wilderness and open prairies. There was little cause for concern about protecting the environment or population and for two centuries, the country's land and water were aggressively used to create a healthy supply of ample food for Americans. In fact, many American families settled in rural areas and made a living as farmers and ranchers, passing the family business down through generations. By the 1930s, the federal government began requiring farmers to idle certain acres of land to prevent oversupply of food and to protect exhausted **soil**.

Since that time, agriculture has become a complex science, as farmers must carefully manage soil and water to lessen risk of degrading the soil and its surrounding environment or depleting water tables beneath the land's surface. In fact, farming and ranching present several environmental challenges that require careful management by farmers and local and federal regulatory agencies that guide their activities. The science of applying principles of ecology to agriculture is called **agroecology**. Those involved in agroecology develop farming methods that use fewer synthetic (man-made) pesticides and fertilizers and encourage organic farming. They also work to conserve energy and water.

Soil **erosion**, converting land to agricultural use, introduction of **fertilizer** and pesticides, animal wastes, and irrigation are parts of farming that can lead to changes in quality or availability of water. An expanding human population has lead to increased farming and accelerated soil erosion. When soil has a low capacity to retain water, farmers must pump **groundwater** up and spray it over crops. After years of doing so, the local water table will eventually fall. This can impact native vegetation in the area.

The industry calls the balance of environment and lessening of agricultural effects sustainability or **sustainable development**. In some parts of the world, like in the High Plains of the United States or parts of Saudi Arabia, populations and agriculture are depleting water aquifers faster than the natural environment can replenish them. Sustainable development involves dedicated, scientifically based plans to ensure that agricultural activity is managed in such a way that aquifers are not prematurely depleted.

Agroforestry is a method of cultivating both crops and teres on the same land. Between rows of trees, farmers plant agricultural crops that generate income during the time it takes the trees to grow mature enough to produce earnings from nuts or lumber.

Increased modernization of agriculture also impacts the environment. Traditional farming practice, which continues in underdeveloped countries today, consists of subsistence agriculture. In subsistence farming, just enough crops and livestock are raised to meet the needs of a particular family. However, today large farms produce food for huge populations. More than half of the world's working population is employed by some agricultural or agriculturally associated industry. Almost 40% of the world's land area is devoted to agriculture (including permanent pasture). The growing use of machines, pesticides and man-made fertilizers have all seriously impacted the environment.

For example, the use of pesticides like DDT in the 1960s were identified as leading to the deaths of certain species of birds. Most western countries banned use of the pesticides and the bird populations soon recovered. Today, use of pesticides is strictly regulated in the United States.

Many more subtle effects of farming occur on the environment. When grasslands and wetlands or forests are converted to crops, and when crops are not rotated, eventually, the land changes to the point that entire species of plants and animals can become threatened. Urbanization also imposes onto farmland and cuts the amount of land available for farming.

Throughout the world, countries and organizations develop strategies to protect the environment, natural habitats and resources while still supplying the food our populations require. In 1992, The **United Nations Conference on Environment and Development** in Rio de Janeiro focused on how to sustain the world's natural resources but balance good policies on environment and community vitality. In the United States, the Department of Agriculture has published its own policy on sustainable development, which works toward balancing economics, environment and social needs concerning agriculture. In 1993, an Executive Order formed the President's Council on Sustainable Development (PCSD) to develop new approaches to achieve economic and environmental goals for public policy in agriculture. Guiding principles include sections on agriculture, forestry and rural community development.

According to the United States **Environmental Protection Agency** (EPA), Agricultural Environmental Management (AEM) is one of the most innovative programs in New York State. The program was begun in June 2000 when Governor George Pataki introduced legislation to the state's Senate and Assembly proposing a partnership to promote farming's good stewardship of land and to provide the funding and support of farmers' efforts. The bill was passed and signed into law by the governor on August 24, 2000.

The purpose of the law is to help farmers develop agricultural environmental management plans that control agricultural pollution and comply with federal, state and local regula-

tions on use of land, water quality, and other environmental concerns. New York's AEM program brings together agencies from state, local, and federal governments, conservation representatives, businesses from the private sector, and farmers. The program is voluntary and offers education, technical assistance, and financial incentives to farmers to participate.

An example of a successful AEM project occurred at a dairy farm in central New York. The farm composted animals' solid wastes, which reduced the amount of waste spread on the fields. This in turn reduced pollution in the local watershed. The New York State Department of Agriculture and Markets oversees the program. It begins when a farmer expresses interest in AEM. Next, the farmer completes a series of five tiers of the program.

In Tier I, the farmer completes a short questionnaire that surveys current farming activities and future plans to identify potential environmental concerns. Tier II involves worksheets that document current activities that promote stewardship of the environment and help prioritize any environmental concerns. In Tier III, a conservation plan is developed that is tailored specifically for the individual farm. The farmer works together with an AEM coordinator and several members of the cooperating agency staff.

Under Tier IV of the AEM program, agricultural agencies and consultants provide the farmer with educational, technical, and financial assistance to implement best management practices for preventing pollution to water bodies in the farm's area. The plans use Natural Resources Conservation Service standards and guidance from cooperating professional engineers. Finally, farmers in the AEM program receive ongoing evaluations to ensure that the plan they have devised helps protect the environment and also ensures viability of the farm business.

Funding for the AEM program comes from a variety of sources, including New York's Clean Water/Clean Air Bond Act and the State Environmental Protection Fund. Local Soil and Water Conservation Districts (SWCDs) also partner in the effort, and farmers can access funds through these districts. The EPA says involvement of the SWCDs has likely been a positive factor in farmers' acceptance of the program.

Though New York is perceived as mostly urban, agriculture is a huge business in the state. The AEM program serves important environmental functions and helps keep New York State's farms economically viable. More than 7,000 farms participate in the program.

Agricultural pollution

The development of modern agricultural practices is one of the great success stories of applied sciences. Improved plowing techniques, new pesticides and fertilizers, and better strains of crops are among the factors that have resulted in significant increases in agricultural productivity.

Yet these improvements have not come without cost to the **environment** and sometimes to human health. Modern agricultural practices have contributed to the **pollution** of air, water, and land. **Air pollution** may be the most memorable, if not the most significant, of these consequences. During the 1920s and 1930s, huge amounts of fertile **topsoil** were blown away across vast stretches of the Great Plains, an area that eventually became known as the **Dust Bowl**. The problem occurred because farmers either did not know about or chose not to use techniques for protecting and conserving their **soil**. The soil then blew away during droughts, resulting not only in the loss of valuable farmland, but also in the pollution of the surrounding **atmosphere**.

Soil conservation techniques developed rapidly in the 1930s, including **contour plowing**, strip cropping, crop rotation, windbreaks, and minimum- or no-tillage farming, and thereby greatly reduced the possibility of **erosion** on such a scale. However, such events, though less dramatic, have continued to occur, and in recent decades they have presented new problems. When top soils are blown away by winds today, they can carry with them the pesticides, herbicides, and other crop **chemicals** now so widely used. In the worst cases, these chemicals have contributed to the collection of air pollutants that endanger the health of plants and animals, including humans. Ammonia, released from the decay of fertilizers, is one example of a compound that may cause minor irritation to the human respiratory system and more serious damage to the health of other animals and plants.

A more serious type of agricultural pollution are the **solid waste** problems resulting from farming and livestock practices. Authorities estimate that slightly over half of all the solid wastes produced in the United States each year—a total of about 2 billion tons (2 billion metric tons)—come

from a variety of agricultural activities. Some of these wastes pose little or no threat to the environment. Crop residue left on cultivated fields and animal manure produced on **rangelands**, for example, eventually decay, returning valuable nutrients to the soil.

Some modern methods of livestock management, however, tend to increase the risks posed by animal wastes. Farmers are raising a larger variety of animals, as well as larger numbers of them, in smaller and smaller areas such as **feedlots** or huge barns. In such cases, large volumes of wastes are generated in these areas. Many livestock managers attempt to sell these waste products or dispose of them in a way that poses no threat to the environment. Yet in many cases the wastes are allowed to accumulate in massive dumps where soluble materials are leached out by rain. Some of these materials then find their way into **groundwater** or surface water, such as lakes and rivers. Some are harmless to the health of animals, though they may contribute to the eutrophication of lakes and ponds. Other materials, however, may have toxic, carcinogenic, or genetic effects on humans and other animals.

The **leaching** of hazardous materials from **animal waste** dumps contributes to perhaps the most serious form of agricultural pollution: the contamination of water supplies. Many of the chemicals used in agriculture today can be harmful to plants and animals. Pesticides and herbicides are the most obvious of these; used by farmers to disable or kill plant and animal pests, they may also cause problems for beneficial plants and animals as well as humans.

Runoff from agricultural land is another serious environmental problem posed by modern agricultural practices. Runoff constitutes a **nonpoint source** of pollution. Rainfall leaches out and washes away pesticides, fertilizers, and other **agricultural chemicals** from a widespread area, not a single source such as a sewer pipe. Maintaining control over nonpoint sources of pollution is an especially difficult challenge. In addition, agricultural land is more easily leached out than is non-agricultural land. When lands are plowed, the earth is broken up into smaller pieces, and the finer the soil particles, the more easily they are carried away by rain. Studies have shown that the **nitrogen** and **phosphorus** in chemical fertilizers are leached out of croplands at a rate about five times higher than from forest woodlands or idle lands.

The accumulation of nitrogen and phosphorus in waterways from chemical fertilizers has contributed to the acceleration of eutrophication of lakes and ponds. Scientists believe that the addition of human-made chemicals such as those in chemical fertilizers can increase the rate of eutrophication by a factor of at least 10. A more deadly effect is the **poisoning** of plants and animals by toxic chemicals leached off of farmlands. The biological effects of such chemicals are commonly magnified many times as they move up a **food chain/web**. The best known example of this phenomenon involved a host of biological problems—from reduced rates of reproduction to malformed animals to increased rates of death—attributed to the use of DDT in the 1950s and 1960s.

Sedimentation also results from the high rate of erosion on cultivated land, and increased sedimentation of waterways poses its own set of environmental problems. Some of these are little more than cosmetic annoyances. For example, lakes and rivers may become murky and less attractive, losing potential as **recreation** sites. However, sedimentation can block navigation channels, and other problems may have fatal results for organisms. Aquatic plants may become covered with sediments and die; marine animals may take in sediments and be killed; and cloudiness from sediments may reduce the amount of sunlight received by aquatic plants so extensively that they can no longer survive.

Environmental scientists are especially concerned about the effects of agricultural pollution on groundwater. Groundwater is polluted by much the same mechanisms as is surface water, and evidence for that pollution has accumulated rapidly in the past decade. **Groundwater pollution** tends to persist for long periods of time. Water flows through an **aquifer** much more slowly than it does through a river, and agricultural chemicals are not flushed out quickly.

Many solutions are available for the problems posed by agricultural pollution, but many of them are not easily implemented. Chemicals that are found to have serious toxic effects on plants and animals can be banned from use, such as DDT in the 1970s, but this kind of decision is seldom easy. Regulators must always assess the relative benefit of using a chemical, such as increased crop yields, against its environmental risks. Such as a risk-benefit analysis means that some chemicals known to have certain deleterious environmental effects remain in use because of the harm that would be done to agriculture if they were banned.

Another way of reducing agricultural pollution is to implement better farming techniques. In the practices of minimum- or no-tillage farming, for example, plowing is reduced or eliminated entirely. Ground is left essentially intact, reducing the rate at which soil and the chemicals it contains are eroded away.

Agricultural Research Service

A branch of the **U.S. Department of Agriculture** charged with the responsibility of agricultural research on a regional or national basis. The Agricultural Research Service (ARS) has a mission to develop new knowledge and technology needed to solve agricultural problems of broad scope and high national priority in order to ensure adequate production of high quality food and agricultural products for the United States. The national research center of the ARS is located at Beltsville, Maryland, consisting of laboratories, land, and other facilities. In addition, there are many other research centers located throughout the United States, such as the U.S. Dairy/Forage Research Center at Madison, Wisconsin. Scientists of the ARS are also located at Land Grant Universities throughout the country where they conduct cooperative research with state scientists.

Agricultural revolution

The development of agriculture has been a fundamental part of the march of civilization. It is an ongoing challenge, for as long as **population growth** continues, mankind will need to improve agricultural production.

The agricultural revolution is actually a series of four major advances, closely linked with other key historical periods. The first, the *Neolithic* or New Stone Age, marks the beginning of sedentary (settled) farming. Much of this history is lost in antiquity, dating back perhaps 10,000 years or more. Still, humans owe an enormous debt to those early pioneers who so painstakingly nourished the best of each year's crop. Archaeologists have found corn cobs a mere 2 in (5.1 cm) long, so different from today's giant ears.

The second major advance came as a result of Christopher Columbus' voyages to the New World. Isolation had fostered the development of two completely independent agricultural systems in the New and Old Worlds. A short list of interchanged crops and animals clearly illustrates the global magnitude of this event; furthermore, the current population explosion began its upswing during this period. From the New World came maize, beans, the "Irish" potato, squash, peanuts, tomatoes, and **tobacco**. From the Old World came wheat, rice, coffee, cattle, horses, sheep, and goats. Maize is now a staple food in Africa. Several Indian tribes in America adopted new lifestyles, notably the Navajo as sheepherders, and the Cheyenne as nomads using the horse to hunt buffalo.

The Industrial Revolution both contributed to and was nourished by agriculture. The greatest agricultural advances came in **transportation**, where first canals, then railroads and steamships made possible the shipment of food from areas of surplus. This in turn allowed more specialization and productivity, but most importantly, it reduced the threat of starvation. The steamship ultimately brought refrigerated meat to Europe from distant Argentina and **Australia**. Without these massive increases in food shipments the exploding populations and greatly increased demand for labor by newly emerging industries could not have been sustained.

In turn the Industrial Revolution introduced major advances in farm technology, such as the cotton gin, mechanical reaper, improved plows, and, in this century, tractors and trucks. These advances enabled fewer and fewer farmers to feed larger and larger populations, freeing workers to fill demands for factory labor and the growing service industries.

Finally, agriculture has fully participated in the scientific advances of the twentieth century. Key developments include hybrid corn, the high responders in tropical lands, described as the "Green Revolution," and current genetic research. Agriculture has benefited enormously from scientific advances in biology, and the future here is bright for applied research, especially involving genetics. Great potential exists for the development of crop strains with greatly improved dietary characteristics, such as higher protein or reduced fat.

Growing populations, made possible by these food surpluses, have forced agricultural expansion onto less and less desirable lands. Because agriculture radically simplifies ecosystems and greatly amplifies **soil erosion**, many areas such as the Mediterranean Basin and tropical forest lands have suffered severe degradation.

Major developments in civilization are directly linked to the agricultural revolution. A sedentary lifestyle, essential to technological development, was both mandated and made possible by farming. Urbanization flourished, which encouraged specialization and division of labor. Large populations provided the energy for massive projects, such as the Egyptian pyramids and the colossal engineering efforts of the Romans.

The plow represented the first lever, both lifting and overturning the soil. The draft animal provided the first in a long line of nonhuman energy sources. Plant and animal selectivity are likely the first application of science and technology toward specific goals. A number of important crops

bear little resemblance to the ancestors from which they were derived. Animals such as the fat-tailed sheep represent thoughtful cultural control of their lineage.

Climate dominates agriculture, second only to **irrigation**. Farmers are especially vulnerable to variations, such as late or early frosts, heavy rains, or **drought**. Rice, wheat, and maize have become the dominant crops globally because of their high caloric yield, versatility within their climate range, and their cultural status as the "staff of life." Many would not consider a meal complete without rice, bread, or tortillas. This cultural influence is so strong that even starving peoples have rejected unfamiliar food. China provides a good example of such cultural differences, with a rice culture in the south and a wheat culture (noodles) in the north.

These crops all need a wet season for germination and growth, followed by a dry season to allow spoilage-free storage. Rice was domesticated in the monsoonal lands of Southeast Asia, while wheat originated in the Fertile Crescent of the Middle East. Historically, wheat was planted in the fall, and harvested in late spring, coinciding with the cycle of wet and dry seasons in the Mediterranean region. Maize needs the heavy summer rains provided by the Mexican highland climate.

Other crops predominate in areas with less suitable climates. These include barley in semiarid lands; oats and potatoes in cool, moist lands; rye in colder climates with short growing seasons; and dry rice on hillsides and drier lands where paddy rice is impractical.

Although food production is the main emphasis in agriculture, more and more industrial applications have evolved. Cloth fibers have been a mainstay, but paper products and many **chemicals** now come from cultivated plants.

The agricultural revolution is also associated with some of mankind's darker moments. In the tropical and subtropical climates of the New World, slave labor was extensive. Close, unsanitary living conditions have fostered plagues of biblical proportions. And the desperate dependence on agriculture is all too vividly evident in the records of historic and contemporary **famine**. As a world, people are never more than one harvest away from global starvation, a fact amplified by the growing understanding of cosmic catastrophes.

Some argue that the agricultural revolution masks the growing hazards of an overpopulated, increasingly contaminated earth. Since the agricultural revolution has been so productive it has more than compensated for the population explosion of the last two centuries. Some appropriately labeled "cornucopians" believe there is yet much potential for increased food production, especially through scientific agriculture and **genetic engineering**. There is much room for optimism, and also for a sobering assessment of the environmental costs of agricultural progress. We must continually strive for answers to the challenges associated with the agricultural revolution.

Agricultural Stabilization and Conservation Service

For the past half century, agriculture in the United States has faced the somewhat unusual and enviable problem of overproduction. Farmers have produced more food than United States citizens can consume, and, as a result, per capita farm income has decreased as the volume of crops has increased. To help solve this problem, the Secretary of Agriculture established the Agricultural Stabilization and Conservation Service on June 5, 1961. The purpose of the service is to administer commodity and land-use programs designed to control production and to stabilize market prices and farm income. The service operates through state committees of three to five members each and committees consisting of three farmers in approximately 3,080 agricultural counties in the nation.

Agroecology

Agroecology is an interdisciplinary field of study that applies ecological principles to the design and management of agricultural systems. Agroecology concentrates on the relationship of agriculture to the biological, economic, political, and social systems of the world.

The combination of agriculture with ecological principles such as biogeochemical cycles, **energy conservation**, and **biodiversity** has led to practical applications that benefit the whole **ecosystem** rather than just an individual crop. For instance, research into **integrated pest management** has developed ways to reduce reliance on pesticides. Such methods include biological or biotechnological controls such as **genetic engineering**, cultural controls such as changes in planting patterns, physical controls such as quarantines to prevent entry of new pests, and mechanical controls such as physically removing weeds or pests.

Sustainable agriculture is another goal of agroecological research. Sustainable agriculture views farming as a total system and stresses the long-term **conservation** of resources. It balances the human need for food with concerns for the **environment** and maintains that agriculture can be carried on without reliance on pesticides and fertilizers.

Agroecology advocates the use of biological controls rather than pesticides to minimize agricultural damage from insects and weeds. Biological controls use natural enemies to control weeds and pests, such as ladybugs that kill aphids. Biological controls include the disruption of the reproductive cycles of pests and the introduction of more biologically diverse organisms to inhibit overpopulation of different agricultural pests.

Agroecological principals shift the focus of agriculture from food production alone to wider concerns, such as environmental quality, food safety, the quality of rural life, humane treatment of livestock, and conservation of air, **soil**, and water. Agroecology also studies how agricultural processes and technologies will be impacted by wider environmental problems such as global warming, **desertification**, or **salinization**.

The entire world population depends on agriculture, and as the number of people continues to grow agroecology is becoming more important, particularly in developing countries. Agriculture is the largest economic activity in the world, and in areas such as sub-Saharan Africa about 75% of the population is involved in some form of it. As population pressures on the world food supply increase, the application of agroecological principles is expected to stem the ecological consequences of traditional agricultural practices such as **pesticide poisoning** and **erosion**.

Agroforestry

Agroforestry is a **land use** system in which woody perennials (trees, shrubs, vines, palms, bamboo, etc.) are intentionally combined on the same land management unit with crops and sometimes animals, either in a spatial arrangement or a temporal sequence. It is based on the premise that woody perennials in the landscape can enhance the productivity and sustainability of agricultural practice. The approach is especially pertinent in tropical and subtropical areas where improper land management and intensive, continuous cropping of land have led to widespread devastation. Agroforestry recognizes the need for an alternative agricultural system that will preserve and sustain productivity. The need for both food and forest products has led to an interest in techniques that combine production of both in a manner that can halt and may even reverse the ruin caused by existing practices.

Although the term agroforestry has come into widespread use only in the last 20–25 years, environmentally sound farming methods similar to those now proposed have been known and practiced in some tropical and subtropical areas for many years. As an example, one type of intercropping found on small **rubber** plantations (less than 25 acres/10 ha), in Malaysia, Thailand, Nigeria, India, and Sri Lanka involves rubber plants intermixed with fruit trees, pepper, coconuts, and arable crops such as soybeans, corn, banana, and groundnut. Poultry may also be included. Unfortunately, in other areas the pressures caused by expanding human and animal populations have led to increased use of destructive farming practices. In the process, inhabitants have further reduced their ability to provide basic food, fiber, fuel, and

timber needs and contributed to even more **environmental degradation** and loss of **soil** fertility.

The successful introduction of agroforestry practices in problem areas requires the cooperative efforts of experts from a variety of disciplines. Along with specialists in forestry, agriculture, **meteorology**, **ecology**, and related fields, it is often necessary to enlist the help of those familiar with local culture and heritage to explain new methods and their advantages. Usually, techniques must be adapted to local circumstances, and research and testing are required to develop viable systems for a particular setting. Intercropping combinations that work well in one location may not be appropriate for sites only a short distance away because of important meteorological or ecological differences. Despite apparent difficulties, agroforestry has great appeal as a means of arresting problems with **deforestation** and declining agricultural yields in warmer climates. The practice is expected to grow significantly in the next several decades. Some areas of special interest include intercropping with coconuts as the woody component, and mixing tree legumes with annual crops.

Agroforestry does not seem to lend itself to mechanization as easily as the large scale grain, soybean and vegetable cropping systems used in industrialized nations because practices for each site are individualized and usually labor-intensive. For these reasons they have had less appeal in areas like the United States and Europe. Nevertheless, temperate zone applications have been developed or are under development. Examples include small scale **organic gardening and farming**, mining wasteland **reclamation**, and **biomass** energy crop production on marginal land.

AIDS

AIDS (acquired immune deficiency syndrome) is an infectious and fatal disease of apparently recent origin. AIDS is *pandemic*, which means that it is worldwide in distribution. A sufficient understanding of AIDS can be gained only by examining its causation (etiology), symptoms, treatments, and the risk factors for transmitting and contracting the disease.

AIDS occurs as a result of infection with the HIV (human immunodeficiency **virus**). HIV is a **ribonucleic acid** (RNA) virus that targets and kills special blood cells, known as helper T-lymphocytes, which are important in immune protection. Depletion of helper T-lymphocytes leaves the AIDS victim with a disabled immune system and at risk for infection by organisms that ordinarily pose no special hazard to the individual. Infection by these organisms is thus opportunistic and is frequently fatal.

The initial infection with HIV may entail no symptoms at all or relatively benign symptoms of short duration that may mimic infectious mononucleosis. This initial period is followed by a longer period (from a few to as many as 10 years) when the infected person is in apparent good health. The HIV infected person, despite the outward image of good health, is in fact contagious, and appropriate care must be exercised to prevent spread of the virus at this time. Eventually the effects of the depletion of helper T cells become manifest. Symptoms include weight loss, persistent cough, persistent colds, diarrhea, periodic fever, weakness, fatigue, enlarged lymph nodes, and malaise. Following this, the AIDS patient becomes vulnerable to chronic infections by opportunistic pathogens. These include, but are not limited to oral yeast infection (thrush), pneumonia caused by the fungus *Pneumocystis carinii*, and infection by several kinds of herpes viruses. The AIDS patient is vulnerable to Kaposi's sarcoma, which is a **cancer** seldom seen except in those individuals with depressed immune systems. Death of the AIDS patient may be accompanied by confusion, dementia, and coma.

There is no cure for AIDS. Opportunistic infections are treated with antibiotics, and drugs such as AZT (azidothymidine), which slow the progress of the HIV infection, are available. But viral diseases in general, including AIDS, do not respond well to antibiotics. Vaccines, however, can provide protection against viral diseases. Research to find a vaccine for AIDS has not yet yielded satisfactory results, but scientists have been encouraged by the development of a vaccine for feline leukemia—a viral disease that has similarities to AIDS. Unfortunately, this does not provide hope of a cure for those already infected with the HIV virus.

Prevention is crucial for a lethal disease with no cure. Thus, modes of transmission must be identified and avoided. Everyone is at risk, males constitute 52% and females 48% of the infected population. In 2002 there are about 40 million people infected with HIV or AIDS, and it is thought that this number will grow to 62 million by 2005. In the United States alone, 40,000 new cases are diagnosed each year. AIDS cases in heterosexual males and women are on the increase, and no sexually active person can be considered "safe" from AIDS any longer. Therefore, everyone who is sexually active should be aware of the principal modes of

transmission of the HIV virus—infected blood, semen from the male and genital tract secretions of the female—and use appropriate means to prevent exposure. While the virus has been identified in tears, saliva, and breast milk, contagions by exposure to those substances seems to be significantly less.

Air and Waste Management Association

Founded in 1907 as the International Association for the Prevention of **Smoke**, this group changed its name several times as the interests of its members changed, becoming the Air and **Waste Management** Association (A&WMA) in the late 1980s. Although an international organization for **environment** professionals in more than 50 countries, the association is most active in North America and most concerned with North American environmental issues. Among its main concerns are **air pollution control**, environmental management, and waste processing and control.

A nonprofit organization that promotes the basic need for a clean environment, A&WMA seeks to educate the public and private sectors of the world by conducting seminars, holding workshops and conferences, and offering continuing education programs for environmental professionals in the areas of **pollution control** and waste management. One of its main goals is to provide "a neutral forum where all viewpoints of an environmental management issue (technical, scientific, economic, social, political and public health) receive equal consideration." Approximately 10–12 specialty conferences are held annually, as well as five or six workshops. The topics continuously revolve and change as new issues arise.

Education is so important to A&WMA that it funds a scholarship for graduate students pursuing careers in fields related to waste management and **pollution** control. Although A&WMA members are all professionals, they seek to educate even the very young by sponsoring essay contests, science fairs, and community activities, and by volunteering to speak to elementary, middle school, and high school audiences on environmental management topics.

The association's 12,000 members, all of whom are volunteers, are involved in virtually every aspect of every A&WMA project. There are 21 association sections across the United States, facilitating meetings at regional and even local levels to discuss important issues. Training seminars are an important part of A&WMA membership, and members are taught the skills necessary to run public outreach programs designed for students of all ages and the general public.

A&WMA's publications deal primarily with **air pollution** and waste management, and include the *Journal of the Air & Waste Management Association*, a scientific monthly; a bimonthly newsletter; a wide variety of technical books; and numerous training manuals and educational videotapes.

Air pollution

Air **pollution** is a general term that covers a broad range of contaminants in the **atmosphere**. Pollution can occur from natural causes or from human activities. Discussions about the effects of air pollution have focused mainly on human health but attention is being directed to environmental quality and amenity as well. Air pollutants are found as gases or particles, and on a restricted scale they can be trapped inside buildings as indoor air pollutants. Urban air pollution has long been an important concern for civic administrators, but increasingly, air pollution has become an international problem.

The most characteristic sources of air pollution have always been **combustion** processes. Here the most obvious pollutant is **smoke**. However, the widespread use of **fossil fuels** have made sulfur and **nitrogen oxides** pollutants of great concern. With increasing use of petroleum-based fuels, a range of organic compounds have become widespread in the atmosphere.

In urban areas, air pollution has been a matter of concern since historical times. Indeed, there were complaints about smoke in ancient Rome. The use of **coal** throughout the centuries has caused cities to be very smoky places. Along with smoke, large concentrations of **sulfur dioxide** were produced. It was this mixture of smoke and sulfur dioxide that typified the foggy streets of Victorian London, paced by such figures as Sherlock Holmes and Jack the Ripper,

whose images remain linked with smoke and fog. Such situations are far less common in the cities of North America and Europe today. However, until recently, they have been evident in other cities, such as Ankara, Turkey, and Shanghai, China, that rely heavily on coal.

Coal is still burnt in large quantities to produce electricity or to refine metals, but these processes are frequently undertaken outside cities. Within urban areas, fuel use has shifted towards liquid and gaseous **hydrocarbons** (petrol and **natural gas**). These fuels typically have a lower concentration of sulfur, so the presence of sulfur dioxide has declined in many urban areas. However, the widespread use of liquid fuels in automobiles has meant increased production of **carbon monoxide**, **nitrogen** oxides, and volatile organic compounds (VOCs).

Primary pollutants such as sulfur dioxide or smoke are the direct **emission** products of the combustion process. Today, many of the key pollutants in the urban atmospheres are secondary pollutants, produced by processes initiated through photochemical reactions. The Los Angeles, California, type **photochemical smog** is now characteristic of urban atmospheres dominated by secondary pollutants.

Although the **automobile** is the main source of air pollution in contemporary cities, there are other equally significant sources. Stationary sources are still important and the oil-burning furnaces that have replaced the older coal-burning ones are still responsible for a range of gaseous emissions and **fly ash**. **Incineration** is also an important source of complex combustion products, especially where this incineration burns a wide range of refuse. These emissions can include **chlorinated hydrocarbons** such as **dioxin**. When **plastics**, which often contain **chlorine**, are incinerated, hydrochloric **acid** results in the waste gas stream. Metals, especially where they are volatile at high temperatures, can migrate to smaller, respirable particles. The accumulation of toxic metals, such as **cadmium**, on fly ash gives rise to concern over harmful effects from incinerator emissions. In specialized incinerators designed to destroy toxic compounds such as PCBs, many questions have been raised about the completeness of this destruction process. Even under optimum conditions where the furnace operation has been properly maintained, great care needs to be taken to control leaks and losses during transfer operations (**fugitive emissions**).

The enormous range of compounds used in modern manufacturing processes have also meant that there has been an ever-widening range of emissions from both from the industrial processes and the combustion of their wastes. Although the amounts of these exotic compounds are often rather small, they add to the complex range of compounds found in the urban atmosphere. Again, it is not only the deliberate loss of effluents through **discharge** from pipes and chimneys that needs attention. Fugitive emissions of volatile substances that leak from valves and **seals** often warrant careful control.

Air pollution control procedures are increasingly an important part of civic administration, although their goals are far from easy to achieve. It is also noticeable that although many urban concentrations of primary pollutants, for example, smoke and sulfur dioxide, are on the decline in developed countries, this is not always true in the developing countries. Here the desire for rapid industrial growth has often lowered urban **air quality**. Secondary air pollutants are generally proving a more difficult problem to eliminate than primary pollutants like smoke.

Urban air pollutants have a wide range of effects, with health problems being the most enduring concern. In the classical polluted atmospheres filled with smoke and sulfur dioxide, a range of bronchial diseases were enhanced. While **respiratory diseases** are still the principal problem, the issues are somewhat more subtle in atmospheres where the air pollutants are not so obvious. In photochemical **smog**, eye irritation from the secondary pollutant **peroxyacetyl nitrate** (PAN) is one on the most characteristic direct effects of the smog. High concentrations of **carbon** monoxide in cities where automobiles operate at high density means that the human heart has to work harder to make up for the oxygen displaced from the blood's hemoglobin by carbon monoxide. This extra stress appears to reveal itself by increased incidence of complaints among people with heart problems. There is a widespread belief that contemporary air pollutants are involved in the increases in **asthma**, but the links between asthma and air pollution are probably rather complex and related to a whole range of factors. **Lead**, from automotive exhausts, is thought by many to be a factor in lowering the IQs of urban children.

Air pollution also affects materials in the urban **environment**. Soiling has long been regarded as a problem, originally the result of the smoke from wood or coal fires, but now increasingly the result of fine black soot from diesel exhausts. The acid gases, particularly sulfur dioxide, increase the rate of destruction of building materials. This is most noticeable with calcareous stones, which are the predominant building material of many important historic structures. Metals also suffer from atmospheric acidity. In the modern photochemical smog, natural rubbers crack and deteriorate rapidly.

Health problems relating to indoor air pollution are extremely ancient. Anthracosis, or **black lung disease**, has been found in mummified lung tissue. Recent decades have witnessed a shift from the predominance of concern about outdoor air pollution into a widening interest in **indoor air quality**.

The production of energy from combustion and the release of solvents is so large in the contemporary world that it causes air pollution problems of a regional and global **nature**. **Acid rain** is now widely observed throughout the world. The sheer quantity of **carbon dioxide** emitted in combustion process is increasing the concentration of carbon dioxide in the atmosphere and enhancing the **greenhouse effect**. Solvents, such as carbon tetrachloride and **aerosol propellants** (such as **chlorofluorocarbons** are now detectable all over the globe and responsible for such problems as **ozone layer depletion**.

At the other end of the scale, it needs to be remembered that gases leak indoors from the polluted outdoor environment, but more often the serious pollutants arise from processes that take place indoors. Here there has been particular concern with indoor air quality as regards to the generation of nitrogen oxides by sources such as gas stoves. Similarly formaldehyde from insulating foams causes illnesses and adds to concerns about our exposure to a substance that may induce **cancer** in the long run. In the last decade it has become clear that **radon** leaks from the ground can expose some members of the public to high levels of this radioactive gas within their own homes. Cancers may also result from the emanation of solvents from consumer products, glues, paints, and mineral fibers (**asbestos**). More generally these compounds and a range of biological materials, animal hair, skin and pollen spores, and dusts can cause allergic reactions in some people. At one end of the spectrum these simply cause annoyance, but in extreme cases, such as found with the bacterium *Legionella*, a large number of deaths can occur.

There are also important issues surrounding the effects of indoor air pollutants on materials. Many industries, especially the electronics industry, must take great care over the purity of indoor air where a speck of dust can destroy a microchip or low concentrations of air pollutants change the composition of surface films in component design. Museums must care for objects over long periods of time, so precautions must be taken to protect delicate dyes from the effects of photochemical smog, paper and books from sulfur dioxide, and metals from sulfide gases.

Air pollution control

The need to control **air pollution** was recognized in the earliest cities. In the Mediterranean at the time of Christ, laws were developed to place objectionable sources of odor and **smoke** downwind or outside city walls. The adoption of **fossil fuels** in thirteenth century England focused particular concern on the effect of **coal** smoke on health, with a number of attempts at regulation with regard to fuel type, chimney heights, and time of use. Given the complexity of the air **pollution** problem it is not surprising that these early attempts at control met with only limited success.

The nineteenth century was typified by a growing interest in urban public health. This developed against a background of continuing industrialization, which saw smoke abatement clauses incorporated into the growing body of sanitary legislation in both Europe and North America. However, a lack of both technology and political will doomed these early efforts to failure, except in the most blatantly destructive situations (for example, industrial settings such as those around Alkali Works in England).

The rise of environmental awareness has reminded people that air pollution ought not to be seen as a necessary product of industrialization. This has redirected responsibility for air pollution towards those who create it. The notion of "making the polluter pay" is seen as a central feature of air **pollution control**. History has also seen the development of a range of broad air pollution control strategies, among them: (1) **Air quality** management strategies that set **ambient air** quality standards so that emissions from various sources can be monitored and controlled; (2) **Emission standards** strategy that sets limits for the amount of pollutant that can be emitted from a given source. These may be set to meet air quality standards, but the strategy is optimally seen as one of adopting best available techniques not entailing excessive costs (BATNEEC); (3) Economic strategies that involve charging the party responsible for the pollution. If the level of charge is set correctly, some polluters will find it more economical to install air pollution control equipment than continue to pollute. Other methods utilize a system of tradable pollution rights; (4) **Cost-benefit analysis**, which attempts to balance economic benefits with environmental costs. This is an appealing strategy but difficult to implement because of its controversial and imprecise nature.

In general air pollution strategies have either been air-quality or emission-based. In the United Kingdom, **emis-**

An industrial complex releases smoke from multiple chimneys. (Photograph by Josef Polleross. The Stock Market. Reproduced by permission.)

sion strategy is frequently used; for example the Alkali and Works Act of 1863 specifies permissible emissions of hydrochloric **acid**. By contrast, the United States has aimed to achieve air quality standards, as evidenced by the **Clean Air Act**. One criticism of using air quality strategy has been that while it improves air in poor areas it leads to degradation in areas with high air quality. Although the emission standards approach is relatively simple, it is criticized for failing to make explicit judgments about air quality and assumes that good practice will lead to an acceptable **atmosphere**.

Until the mid-twentieth century, legislation was primarily directed towards industrial sources, but the passage of the United Kingdom Clean Air Act (1956), which followed the disastrous **smog** of December 1952, directed attention towards domestic sources of smoke. While this particular act may have reinforced the improvements already under way, rather than initiating improvements, it has served as a catalyst for much subsequent legislative thinking. Its mode of operation was to initiate a change in fuel, perhaps one of the oldest methods of control. The other well-tried aspects were the creation of smokeless zones and an emphasis on tall chimneys to disperse the pollutants.

As simplistic as such passive control measures seem, they remain at the heart of much contemporary thinking. Changes from coal and oil to the less polluting gas or electricity have contributed to the reduction in smoke and **sulfur dioxide** concentrations in cities all around the world. Industrial zoning has often kept power and large manufacturing plants away from centers of human population, and "superstacks," chimneys of enormous height are now quite common. Successive changes in automotive fuels—lead-free **gasoline**, low volatility gas, **methanol**, or even the interest in the electric automobile—are further indications of continued use of these methods of control.

There are more active forms of air pollution control that seek to clean up the exhaust gases. The earliest of these were smoke and grit arrestors that came into increasing use in large electrical stations during the twentieth century. Notable here were the **cyclone** collectors that removed large particles by driving the exhaust through a tight spiral that

threw the grit outward where it could be collected. Finer particles could be removed by **electrostatic precipitation**. These methods were an important part of the development of the modern pulverized fuel power station. However they failed to address the problem of gaseous emissions. Here it has been necessary to look at burning fuel in ways that reduce the production of **nitrogen oxides**. Control of sulfur dioxide emissions from large industrial plants can be achieved by desulfurization of the flue gases. This can be quite successful by passing the gas through towers of solid absorbers or spraying solutions through the exhaust gas stream. However, these are not necessarily cheap options.

Catalytic converters are also an important element of active attempts to control air pollutants. Although these can considerably reduce emissions, they have to be offset against the increasing use of the **automobile**. There is much talk of the development of zero pollution vehicles that do not emit any pollutants.

Legislation and control methods are often associated with monitoring networks that assess the effectiveness of the strategies and inform the general public about air quality where they live. A balanced approach to the control of air pollution in the future may have to look far more broadly than simply at technological controls. It will become necessary to examine the way people structure their lives in order to find more effective solutions to air pollution.

Air pollution index

The **air pollution** index is a value derived from an **air quality** scale which uses the measured or predicted concentrations of several criteria pollutants and other air quality indicators, such as coefficient of **haze** (COH) or **visibility**. The best known index of air **pollution** is the pollutant standard index (PSI).

The PSI has a scale that spans from 0 to 500. The index represents the highest value of several subindices; there is a subindex for each pollutant, or in some cases, for a product of pollutant concentrations and a product of pollutant concentrations and COH. If a pollutant is not monitored, its subindex is not used in deriving the PSI. In general, the subindex for each pollutant can be interpreted as follows

Air Pollution Stages

Index Value	Interpretations
0	No concentration
100	National Ambient Air Quality Standard
200	Alert
300	Warning
400	Emergency
500	Significant harm

The subindex of each pollutant or pollutant product is derived from a PSI nomogram which matches concentrations with subindex values. The highest subindex value becomes the PSI. The PSI has five health-related categories:

PSI Range	Category
0 to 50	Good
50 to 100	Moderate
100 to 200	Unhealthful
200 to 300	Very unhealthful
300 to 500	Hazardous

Air quality

Air quality is determined with respect to the total **air pollution** in a given area as it interacts with meteorological conditions such as humidity, temperature and wind to produce an overall atmospheric condition. Poor air quality can manifest itself aesthetically (as a displeasing odor, for example), and can also result in harm to plants, animals, people, and even damage to objects.

As early as 1881, cities such as Chicago, Illinois, and Cincinnati, Ohio, had passed laws to control some types of **pollution**, but it wasn't until several air pollution catastrophes occurred in the twentieth century that governments began to give more attention to air quality problems. For instance, in 1930, **smog** trapped in the Meuse River Valley in Belgium caused 60 deaths. Similarly, in 1948, smog was blamed for 20 deaths in Donora, Pennsylvania. Most dramatically, in 1952 a sulfur-laden fog enshrouded London for five days and caused as many as 4,000 deaths over two weeks.

Disasters such as these prompted governments in a number of industrial countries to initiate programs to protect air quality. The year of the London tragedy, the United States passed the **Air Pollution Control** Act granting funds to assist the states in controlling airborne pollutants. In 1963, the **Clean Air Act**, which began to place authority for air quality into the hands of the federal government, was established. Today the Clean Air Act, with its 1970 and 1990 amendments, remains the principal air quality law in the United States.

The Act established a **National Ambient Air Quality Standard** under which federal, state, and local monitoring stations at thousands of locations, together with temporary stations set up by the **Environmental Protection Agency** (EPA) and other federal agencies, directly measure pollutant concentrations in the air and compare those concentrations with national standards for six major pollutants: **ozone**, **carbon monoxide**, **nitrogen oxides**, **lead**, particulates, and **sulfur dioxide**. When the air we breathe contains amounts of these pollutants in excess of EPA standards, it is deemed unhealthy, and regulatory action is taken to reduce the pollution levels.

In addition, urban and industrial areas maintain an **air pollution index**. This scale, a composite of several pollutant levels recorded from a particular monitoring site or sites, yields an overall air quality value. If the index exceeds certain values public warnings are given; in severe instances residents might be asked to stay indoors and factories might even be closed down.

While such air quality emergencies seem increasingly rare in the United States, developing countries, as well as Eastern European nations, continue to suffer poor air quality, especially in urban areas such as Bangkok, Thailand and **Mexico City, Mexico**. In Mexico City, for example, seven out of 10 newborns have higher lead levels in their blood than the World Health Organization considers acceptable. At present, many **Third World** countries place national economic development ahead of pollution control—and in many countries with rapid industrialization, high **population growth**, or increasing per capita income, the best efforts of governments to maintain air quality are outstripped by rapid proliferation of automobiles, escalating factory emissions, and runaway urbanization.

For all the progress the United States has made in reducing **ambient air** pollution, *indoor* air pollution may pose even greater risks than all of the pollutants we breathe outdoors. The **Radon** Gas and **Indoor Air Quality** Act of 1986 directed the EPA to research and implement a public information and technical assistance program on indoor air quality. From this program has come monitoring equipment to measure an individual's "total exposure" to pollutants both in indoor and outdoor air. Studies done using this equipment have shown indoor exposures to toxic air pollutants far exceed outdoor exposures for the simple reason that most people spend 90% of their time in office buildings, homes, and other enclosed spaces. Moreover, nationwide **energy conservation** efforts following the oil crisis of the 1970s led to building designs that trap pollutants indoors, thereby exacerbating the problem.

Air quality control region

The **Clean Air Act** defines an **air quality** control region (AQCR) as a contiguous area where air quality, and thus **air pollution**, is relatively uniform. In those cases where **topography** is a factor in air movement, AQCRs often correspond with airsheds. AQCRs may consist of two or more cities, counties or other governmental entities, and each region is required to adopt consistent **pollution control** measures across the political jurisdictions involved. AQCRs may even cross state lines and, in these instances, the states must cooperate in developing **pollution** control strategies. Each AQCR is treated as a unit for the purposes of pollution reduction and achieving National Ambient Air Quality Standards. As of 1993, most AQCRs had achieved national air quality standards; however the remaining AQCRs where standards had not been achieved were a significant group, where a large percentage of the United States population dwelled. AQCRs involving major metro areas like Los Angeles, New York, Houston, Denver, and Philadelphia were not achieving air quality standards because of **smog**, motor vehicle emissions, and other pollutants.

Air quality criteria

The relationship between the level of exposure to air pollutant concentrations and the adverse effects on health or public welfare associated with such exposure. **Air quality** criteria are critical in the development of **ambient air** quality standards which define levels of acceptably safe exposure to an air pollutant.

Air-pollutant transport

Air-pollutant transport is the advection or horizontal convection of air pollutants from an area where **emission** occurs to a downwind receptor area by local or regional winds. It is sometimes referred to as atmospheric transport of air pollutants. This movement of **air pollution** is often simulated with computer models for point sources as well as for large diffuse sources such as urban regions.

In some cases, strong regional winds or low-level nocturnal jets can carry pollutants hundreds of miles from source areas of high emissions. The possibility of transport over such distances can be increased through topographic channeling of winds through valleys. Air-pollutant transport over such distances is often referred to as long-range transport.

Air-pollutant transport is an important consideration in **air quality** planning. Where such impact occurs, the success of an air quality program may depend on the ability of **air pollution control** agencies to control upwind sources.

Airshed

A geographical region, usually a topographical basin, that tends to have uniform **air quality**. The air quality within an airshed is influenced predominantly by **emission** activities native to that airshed, since the elevated **topography** around the basin constrains horizontal air movement. Pollutants move from one part of an airshed to other parts fairly quickly, but are not readily transferred to adjacent airsheds. An airshed tends to have a relatively uniform **climate** and relatively uniform meteorological features at any given point in time.

Alar

Alar is the trade name for the chemical compound daminozide, manufactured by the Uniroyal Chemical Company. The compound has been used since 1968 to keep apples from falling off trees before they are ripe and to keep them red and firm during storage. As late as the early 1980s, up to 40% of all red apples produced in the United States were treated with Alar.

In 1985, the **Environmental Protection Agency** (EPA) found that UDMH (N,N-dimethylhydrazine), a compound produced during the breakdown of daminozide, was a **carcinogen**. UDMH was routinely produced during the processing of apples, as in the production of apple juice and apple sauce, and the EPA suggested a ban on the use of Alar by apple growers. An outside review of the EPA studies, however, suggested that they were flawed, and the ban was not instituted. Instead, the agency recommended that Uniroyal conduct further studies on possible health risks from daminozide and UDMH.

Even without a ban, Uniroyal felt the impact of the EPA's research well before its own studies were concluded. Apple growers, fruit processors, legislators, and the general public were all frightened by the possibility that such a widely used chemical might be carcinogenic. Many growers, processors, and store owners pledged not to use the compound nor to buy or sell apples on which it had been used. By 1987, sales of Alar had dropped by 75%.

In 1989, two new studies again brought the subject of Alar to the public's attention. The consumer research organization Consumers' Union found that, using a very sensitive test for the chemical, 11 of 20 red apples they tested contained Alar. In addition, 23 of 44 samples of apple juice tested contained detectable amounts of the compound. The **Natural Resources Defense Council** (NRDC) announced their findings on the compound at about the same time. The NRDC concluded that Alar and certain other **agricultural chemicals** pose a threat to children about 240 times higher than the one-in-a-million risk traditionally used by the EPA to determine the acceptability of a product used in human foods.

The studies by the NRDC and the Consumers' Union created a panic among consumers, apple growers, and apple processors. Many stores removed all apple products from their shelves, and some growers destroyed their whole crop of apples. The industry suffered millions of dollars in damage. Representatives of the apple industry continued to question how much of a threat Alar truly posed to consumers, claiming that the carcinogenic risks identified by the EPA, NRDC, and Consumers' Union were greatly exaggerated. But in May of that same year, the EPA announced interim data from its most recent study, which showed that UDMH caused blood-vessel tumors in mice. The agency once more declared its intention to ban Alar, and within a month, Uniroyal announced it would end sales of the compound in the United States.

Alaska Highway

The Alaska Highway, sometimes referred to as the Alcan (*Al*aska-*Can*ada) Highway, is the final link of a binational

transportation corridor that provides an overland route between the lower United States and Alaska. The first, all-weather, 1,522-mi (2,451 km) Alcan Military Highway was hurriedly constructed during 1942–1943 to provide land access between Dawson Creek, a Canadian village in northeastern British Columbia, and Fairbanks, a town on the Yukon River in central Alaska. Construction of the road was motivated by perception of a strategic, but ultimately unrealized, Japanese threat to maritime supply routes to Alaska during World War II.

The route of the Alaska Highway extended through what was then a **wilderness**. An aggressive technical vision was supplied by the United States **Army Corps of Engineers** and the civilian U.S. Public Roads Administration and labor by approximately 11,000 American soldiers and 16,000 American and Canadian civilians. In spite of the extraordinary difficulties of working in unfamiliar and inhospitable terrain, the route was opened for military passage in less than two years. Among the formidable challenges faced by the workers was a need to construct 133 bridges and thousands of smaller culverts across energetic watercourses, the infilling of alignments through a boggy muskeg capable of literally swallowing bulldozers, and working in winter temperatures that were so cold that vehicles were not turned off for fear they would not restart (steel dozer-blades became so brittle that they cracked upon impact with rock or frozen ground).

In hindsight, the planning and construction of the Alaska Highway could be considered an unmitigated environmental debacle. The enthusiastic engineers were almost totally inexperienced in the specialized techniques of arctic construction, especially about methods dealing with **permafrost**, or permanently frozen ground. If the integrity of permafrost is not maintained during construction, then this underground, ice-rich matrix will thaw and become unstable, and its water content will run off. An unstable morass could be produced by the resulting **erosion**, mudflow, slumping, and thermokarst-collapse of the land into subsurface voids left by the loss of water. Repairs were very difficult, and reconstruction was often unsuccessful, requiring abandonment of some original alignments. Physical and biological disturbances caused terrestrial landscape scars that persist to this day and will continue to be visible (especially from the air) for centuries. Extensive reaches of aquatic **habitat** were secondarily degraded by erosion and/or **sedimentation**. The much more careful, intensively scrutinized, and ecologically sensitive approaches used in the Arctic today, for example during the planning and construction of the trans Alaska pipeline, are in marked contrast with the unfettered and free-wheeling engineering associated with the initial construction of the Alaska Highway.

Map of the Alaska (Alcan) Highway. (Line drawing by Laura Gritt Lawson. Reproduced by permission.)

The Alaska Highway has been more-or-less continuously upgraded since its initial completion and was opened to unrestricted traffic in 1947. Non-military benefits of the Alaska Highway include provision of access to a great region of the interior of northwestern North America. This access fostered economic development through mining, forestry, trucking, and tourism, as well as helping to diminish the perception of isolation felt by many northern residents living along the route.

Compared with the real dangers of vehicular passage along the Alaska Highway during its earlier years, today the route safely provides one of North America's most spectacular **ecotourism** opportunities. Landscapes range from alpine **tundra** to expansive boreal forest, replete with abundantly cold and vigorous streams and rivers. There are abundant opportunities to view large mammals such as moose (*Alces alces*), caribou (*Rangifer tarandus*), and bighorn sheep (*Ovis canadensis*), as well as charismatic smaller mammals and birds and a wealth of interesting arctic, boreal, and alpine **species** of plants.

Alaska National Interest Lands Conservation Act (1980)

Commonly known as the Alaska Lands Act, The Alaska National Interest Lands Conservation Act (ANILCA) law protected 104 million acres (42 million ha), or 28%, of the state's 375 million acres (152 million ha) of land. The law added 44 million acres (18 million ha) to the **national park** system, 55 million acres (22.3 million ha) to the fish and **wildlife refuge** system, 3 million acres (1.2 million ha) to the **national forest** system, and made 26 additions to the national wild and scenic rivers system. The law also designated 56.7 million acres (23 million ha) of land as **wilderness**, with the stipulation that 70 million acres (28.4 million ha) of additional land be reviewed for possible wilderness designation.

The genesis of this act can be traced to 1959, when Alaska became the forty-ninth state. As part of the statehood act, Alaska could choose 104 million acres (42.1 million ha) of federal land to be transferred to the state. This selection process was halted in 1966 to clarify land claims made by Alaskan **indigenous peoples**. In 1971, the Alaska Native Claims Settlement Act (ANSCA) was passed to satisfy the native land claims and allow the state selection process to continue. This act stipulated that the Secretary of the Interior could withdraw 80 million acres (32.4 million ha) of land for protection as national parks and monuments, fish and **wildlife** refuges, and national forests, and that these lands would not be available for state or native selection. Congress would have to approve these designations by 1978. If Congress failed to act, the state and the natives could select any lands not already protected. These lands were referred to as national interest or d-2 lands.

Secretary of the Interior Rogers Morton recommended 83 million acres (33.6 million ha) for protection in 1973, but this did not satisfy environmentalists. The ensuing conflict over how much and which lands should be protected, and how these lands should be protected, was intense. The environmental community formed the Alaska Coalition, which by 1980 included over 1,500 national, regional, and local organizations with a total membership of 10 million people. Meanwhile, the state of Alaska and development-oriented interests launched a fierce and well-financed campaign to reduce the area of protected land.

In 1978, the House passed a bill protecting 124 million acres (50.2 million ha). The Senate passed a bill protecting far less land, and House-Senate negotiations over a compromise broke down in October. Thus, Congress would not act before the December 1978 deadline. In response, the executive branch acted. Department of the Interior Secretary Cecil Andrus withdrew 110 million acres (44.6 million ha) from state selection and mineral entry. President Jimmy Carter then designated 56 million acres (22.7 million ha) of these lands as national monuments under the authority of the Antiquities Act. Forty million additional acres (16.2 million ha) were withdrawn as fish and wildlife refuges, and 11 million acres (4.5 million ha) of existing national forests were withdrawn from state selection and mineral entry. Carter indicated that he would rescind these actions once Congress had acted.

In 1979, the House passed a bill protecting 127 million acres (51.4 million ha). The Senate passed a bill designating 104 million acres (42.1 million ha) as national interest lands in 1980. Environmentalists and the House were unwilling to reduce the amount of land to be protected. In November, however, Ronald Reagan was elected President, and the environmentalists and the House decided to accept the Senate bill rather than face the potential for much less land under a President who would side with development interests. President Carter signed ANILCA into law on December 2, 1980.

ANILCA also mandated that the U.S. Geological Service (USGS) conduct biological and **petroleum** assessments of the coastal plain section of the **Arctic National Wildlife Refuge**, 19.8 million acres (8 million ha) known as area 1002. While the USGS did determine a significant quantity of oil reserves in the area, they also reported that petroleum development would adversely impact many native **species**, including caribou (*Rangifer tarandus*), snow geese (*Chen caerulescens*), and muskoxen (*Ovibos moschatus*). In 2001, the Bush administration unveiled a new **energy policy** that would open up this area to oil and **natural gas** exploration. In June 2002, a House version of the energy bill (H.R.4) that favors opening ANWR to drilling and a Senate version (S.517) that does not were headed into conference to reconcile the differences between the two bills.

Albedo

The reflecting power of a surface, expressed as a ratio of reflected radiation to incident or incoming radiation; it is sometimes expressed as a percentage. Albedo is also called the "reflection coefficient" and derives from the Latin root word *albus*, which means whiteness. Sometimes expressed as a percentage, albedo is more commonly measured as a fraction on a scale from zero to one, with a value of one denoting a completely reflective, white surface, while a value of zero would describe an absolutely black surface that reflects no light rays.

Albedo varies with surface characteristics such as color and composition, as well as with the angle of the sun. The albedo of natural earth surface features such as oceans, forests, deserts, and crop canopies varies widely. Some measured values of albedo for various surfaces are shown below:

Types of Surface	Albedo
Fresh, dry snow cover	0.80–0.95
Aged or decaying snow cover	0.40–0.70
Oceans	0.07–0.23
Dense clouds	0.70–0.80
Thin clouds	0.25–0.50
Tundra	0.15–0.20
Desert	0.25–0.29
Coniferous forest	0.10–0.15
Deciduous forest	0.15–0.20
Field crops	0.20–0.30
Bare dark soils	0.05–0.15

The albedo of clouds in the **atmosphere** is important to life on Earth because extreme levels of radiation absorbed by the earth would make the planet uninhabitable; at any moment in time about 50% of the planet's surface is covered by clouds. The mean albedo for the earth, called the planetary albedo, is about 30–35%.

[*Mark W. Seeley*]

Algal bloom

Algae are simple, single-celled, filamentous aquatic plants; they grow in colonies and are commonly found floating in ponds, lakes, and oceans. Populations of algae fluctuate with the availability of nutrients, and a sudden increase in nutrients often results in a profusion of algae known as algal bloom.

The growth of a particular algal **species** can be both sudden and massive. Algal cells can increase to very high densities in the water, often thousands of cells per milliliter, and the water itself can be colored brown, red, or green. Algal blooms occur in freshwater systems and in marine environments, and they usually disappear in a few days to a few weeks. These blooms consume oxygen, increase turbidity, and clog lakes and streams. Some algal species release water-soluble compounds that may be toxic to fish and shellfish, resulting in **fish kills** and **poisoning** episodes.

Algal groups are generally classified on the basis of the pigments that color their cells. The most common algal groups are blue-green algae, green algae, red algae, and brown algae. Algal blooms in freshwater lakes and ponds tend to be caused by blue-green and green algae. The excessive amounts of nutrients that cause these blooms are often the result of human activities. For example, **nitrates** and **phosphates** introduced into a lake from **fertilizer runoff** during a storm can cause rapid algal growth. Some common blue-green algae known to cause blooms as well as release nerve **toxins** are *Microcystis, Nostoc,* and *Anabaena.*

Red tides in coastal areas are a type of algal bloom. They are common in many parts of the world, including the **New York Bight**, the Gulf of California, and the Red Sea. The causes of algal blooms are not as well understood in marine environments as they are in freshwater systems. Although human activities may well have an effect on these events, weather conditions probably play a more important role: turbulent storms that follow long, hot, dry spells have often been associated with algal blooms at sea. Toxic red tides most often consist of genera from the dinoflagellate algal group such as *Gonyaulax* and *Gymnodinium.* The potency of the toxins has been estimated to be 10 to 50 times higher than cyanide or curare, and people who eat exposed shellfish may suffer from paralytic shellfish poisoning within 30 minutes of consumption. A fish kill of 500 million fish was reported from a **red tide** in Florida in 1947. A number of blue-green algal genera such as *Oscillatoria* and *Trichodesmium* have also been associated with red blooms, but they

are not necessarily toxic in their effects. Some believe that the blooms caused by these genera gave the Red Sea its name.

The economic and health consequences of algal blooms can be sudden and severe, but the effects are generally not long lasting. There is little evidence that algal blooms have long-term effects on **water quality** or **ecosystem** structure.

Algicide

The presence of nuisance algae can cause unsightly appearance, odors, slime, and coating problems in aquatic media. Algicides are chemical agents used to control or eradicate the growth of algae in aquatic media such as industrial tanks, swimming pools, and lakes. These agents used may vary from simple inorganic compounds such as **copper** sulphate which are broad-spectrum in effect and control a variety of algal groups to complex organic compounds that are targeted to be species-specific in their effects. Algicides usually require repeated application or continuous application at low doses in order to maintain effective control.

Aline, Tundra

see **Tundra**

Allelopathy

Derived from the Greek words *allelo* (other) and *pathy* (causing injury to), allelopathy is a form of **competition** among plants. One plant produces and releases a chemical into the surrounding **soil** that inhibits the germination or growth of other **species** in the immediate area. These chemical substances are both acids and bases and are called secondary compounds. For example, black walnut (*Jugans nigra*) trees release a chemical called juglone that prevents other plants such as tomatoes from growing in the immediate area around each tree. In this way, plants such as black walnut reduce competition for space, nutrients, water, and sunlight.

Allergen

Any substance that can bring about an allergic response in an organism. Hay fever and **asthma** are two common allergic responses. The allergens that evoke these responses include pollen, **fungi**, and dust. Allergens can be described as host-specific agents in that a particular allergen may affect some individuals, but not others. A number of air pollutants are known to be allergens. Formaldehyde, thiocyanates, and epoxy resins are examples. People who are allergic to natural allergens, such as pollen, are more inclined to be sensitive also to synthetic allergens, such as formaldehyde.

Alligator, American

The American alligator (*Alligator mississippiensis*) is a member of the reptilian family Crocodylidae, which consists of 21 **species** found in tropical and subtropical regions throughout the world. It is a species that has been reclaimed from the brink of **extinction**.

Historically, the American alligator ranged in the Gulf and Atlantic coast states from Texas to the Carolinas, with rather large populations concentrated in the swamps and river bottomlands of Florida and Louisiana. From the late nineteenth century into the middle of the twentieth century, the population of this species decreased dramatically. With no restrictions on their activities, hunters killed alligators as pests or to harvest their skin, which was highly valued in the leather trade. The American alligator was killed in such great numbers that biologists predicted its probable extinction. It has been estimated that about 3.5 million of these reptiles were slaughtered in Louisiana between 1880 and 1930. The population was also impacted by the fad of selling young alligators as pets, principally in the 1950s.

States began to take action in the early 1960s to save the alligator from extinction. In 1963 Louisiana banned all legalized **trapping**, closed the alligator **hunting** season, and stepped up enforcement of game laws against poachers. By the time the **Endangered Species Act** was passed in 1973, the species was already experiencing a rapid recovery. Because of the successful re-establishment of alligator populations, its endangered classification was downgraded in several southeastern states, and there are now strictly regulated seasons that allow alligator trapping. Due to the persistent demand for its hide for leather goods and an increasing market for the reptile's meat, alligator farms are now both legal and profitable.

An American alligator (*Alligator mississippiensis*). (Photograph by B. Arroyo. U. S. Fish & Wildlife Service. Reproduced by permission.)

Human fascination with large, dangerous animals, along with the American alligator's near extinction, have made it one of North America's best studied reptile species. Population pressures, primarily resulting from being hunted so ruthlessly for decades, have resulted in a decrease in the maximum size attained by this species. The growth of a reptile is indeterminate, and they continue to grow as long as they are alive, but old adults from a century ago attained larger sizes than their counterparts do today. The largest recorded American alligator was an old male killed in January 1890, in Vermilion Parish, Louisiana, which measured 19.2 ft (6 m) long. The largest female ever taken was only about half that size.

Alligators do not reach sexual maturity until they are about 6 ft (1.3 m) long and nearly 10 years old. Females construct a nest mound in which they lay about 35–50 eggs. The nest is usually 5–7 ft (1.5–2.1 m) in diameter and 2–3 ft (0.6–0.9 m) high, and decaying vegetation produces heat which keeps the eggs at a fairly constant temperature during incubation. The young stay with their mother through their first winter, striking out on their own when they are about 1.5 ft (0.5 m) in length.

Alpha particle

A particle emitted by certain kinds of radioactive materials. An alpha particle is identical to the nucleus of a helium atom, consisting of two protons and two neutrons. Some common alpha-particle emitters are uranium-235, uranium-238, radium-226, and radon-222. Alpha particles have relatively low penetrating power. They can be stopped by a thin sheet of paper or by human skin. They constitute a health problem, therefore, only when they are taken into the body. The inhalation of alpha-emitting **radon** gas escaping from bedrock into houses in some areas is thought to constitute a health hazard.

Alternative energy sources

Coal, oil, and **natural gas** provide over 85% of the total primary energy used around the world. Although figures differ in various countries, nuclear reactors and hydroelectric power together produce less than 10% of the total world energy. Wind power, active and passive solar systems, and **geothermal energy** are examples of alternative energy sources. Collectively, these make up the final small fraction of total energy production.

The exact contribution alternative energy sources make to the total primary energy used around the world is not known. Conservative estimates place their share at 3–4%, but some energy experts dispute these figures. **Amory Lovins** has argued that the **statistics** collected are based primarily on large **electric utilities** and the regions they serve. They fail to account for areas remote from major power grids, which are more likely to use **solar energy**, **wind energy**, or other sources. When these areas are taken into consideration, Lovins claims, alternative energy sources contribute as much as 11% to the total primary energy used in the United States. Animal manure, furthermore, is widely used as an energy source in India, parts of China, and many African nations, and when this is taken into account the percentage of the worldwide contribution alternative sources make to energy production could rise as high as 10–15%. Now an alternative energy source, wind power is one of the earliest forms of energy used by humankind. Wind is caused by the uneven heating of the earth's surface, and its energy is equal to about 2% of the solar energy that reaches the earth. In quantitative terms, the amount of kinetic energy within the earth's **atmosphere** is equal to about 10,000 trillion kilowatt hours.

The kinetic energy of wind is proportional to the wind velocity, and the ideal location for a windmill generator is an area with constant and relatively fast winds and no obstacles such as buildings or trees. An efficient windmill can produce 175 watts per square meter of propeller blade area at a height of 75 ft (25 m). The estimated cost of generating one kilowatt hour by wind power is about eight cents, as compared to five cents for hydropower and 15 cents for **nuclear power**. The largest two utilities in California purchase wind-generated electricity, and though this state leads the country in the utilization of wind power, Denmark leads the world. The Scandinavian nation has refused to use nuclear power, and it expects to obtain 10% of its energy needs from windmills.

Solar energy can be utilized either directly as heat or indirectly by converting it to electrical power using photovoltaic cells. Greenhouses and solariums are the most common examples of the direct use of solar energy, with glass windows concentrating the visible light from the sun but restricting the heat from escaping. Flatplate collectors are another direct method, and mounted on rooftops they can provide one third of the energy required for space heating. Windows and collectors alone are considered passive systems; an active solar system uses a fan, pump, or other machinery to transport the heat generated from the sun.

Photovoltaic cells are made of semiconductor materials such as silicon. These cells are capable of absorbing part of the solar flux to produce a direct electric current with about 14% efficiency. The current cost of producing photovoltaic current is about four dollars a watt. However, a thin-film technology is being perfected for the production of these cells, and the cost per watt will eventually be reduced because less materials will be required. Photovoltaics are now being used economically in lighthouses, boats, rural villages, and other remote areas. Large solar systems have been most effective using trackers that follow the sun or mirror reflectors that concentrate its rays.

Geothermal energy is the natural heat generated in the interior of the earth, and like solar energy it can also be used directly as heat or indirectly to generate electricity. Steam is classified as either dry (no water droplets), or wet (mixed with water). When it is generated in certain areas containing corrosive sulfur compounds, it is known as "sour steam," and when generated in areas that are free of sulfur it is known as "sweet steam." Geothermal energy can be used to generate electricity by the flashed steam method, in which high temperature geothermal brine is used as a heat exchanger to convert injected water into steam. The produced steam is used to turn a turbine. When geothermal

wells are not hot enough to create steam, a fluid which evaporates at a much lower temperature than water, such as isobutane or ammonia, can be placed in a closed system where the geothermal heat provides the energy to evaporate the fluid and run the turbine.

There are 20 countries worldwide that utilize this energy source, and they include the United States, Mexico, Italy, Iceland, Japan, and the former Soviet Union. Unlike solar energy and wind power, geothermal energy is not free of environmental impact. It contributes to **air pollution**, it can emit dissolved salts and, in some cases, toxic **heavy metals** such as **mercury** and **arsenic**.

Though there are several ways of utilizing energy from the ocean, the most promising are the harnessing of **tidal power** and **ocean thermal energy conversion**. The power of ocean tides is based on the difference between high and low water. In order for tidal power to be effective the differences in height need to be very great, more than 15 ft (3 m), and there are only a few places in the world where such differences exist. These include the **Bay of Fundy** and a few sites in China. Ocean thermal energy conversion utilizes temperature changes rather than tides. Ocean temperature is stratified, especially near the tropics, and the process takes advantage of this fact by using a fluid with a low boiling point, such as ammonia. The vapor from the fluid drives a turbine, and cold water from lower depths is pumped up to condense the vapor back into liquid. The electrical power generated by this method can be shipped to shore or used to operate a floating plant such as a cannery.

Other sources of alternative energy are currently being explored, some of which are still experimental. These include harnessing the energy in **biomass** through the production of wood from trees or the production of **ethanol** from crops such as sugar cane or corn. **Methane** gas can be generated from the **anaerobic** breakdown of **organic waste** in sanitary landfills and from **wastewater** treatment plants. With the cost of **garbage** disposal rapidly increasing, the burning of garbage is becoming a viable option as an energy source. Adequate air **pollution** controls are necessary, but trash can be burned to heat buildings, and municipal garbage is currently being used to generate electricity in Hamburg, Germany. In an experimental method known as *magnetohydrodynamics*, hot gas is ionized (potassium and sulfur) and passed through a strong magnetic field where it produces an electrical current. This process contains no moving parts and has an efficiency of 20–30%.

Ethanol and **methanol** can be produced from biomass and used in **transportation**; in fact, methanol currently powers Indianapolis race cars. **Hydrogen** could be valuable if problems of supply and storage can be solved. It is very clean-burning, forming water, and may be combined with oxygen in **fuel cells** to generate electricity. Also, it is not nearly as explosive as **gasoline**.

Of all the alternative sources, **energy conservation** is perhaps the most important, and improving **energy efficiency** is the best way to meet energy demands without adding to air and **water pollution**. One reason the United States survived the energy crises of the 1970s was that they were able to curtail some of their immense waste. Relatively easy lifestyle alterations, vehicle improvements, building insulation, and more efficient machinery and appliances have significantly reduced their potential energy demand. Experts have estimated that it is possible to double the efficiency of electric motors, triple the intensity of light bulbs, quadruple the efficiency of refrigerators and air conditioners, and quintuple the gasoline mileage of automobiles. Several **automobile** manufacturers in Europe and Japan have already produced prototype vehicles with very high gasoline mileage. Volvo has developed the LCP 2000, a passenger sedan that holds four to five people, meets all United States safety standards, accelerates from 0–50 MPH (0–80.5 km/hr) in 11 seconds, and has a high fuel efficiency rating. Alternative fuels will be required to meet future energy needs. Enormous investments in new technology and equipment will be needed, and potential supplies are uncertain, but there is clearly hope for an energy-abundant future.

Aluminum

Aluminum, a light metal, comprises about 8% of the earth's crust, ranking as the third-most abundant element after oxygen (47%) and silicon (28%). Virtually all environmental

aluminum is present in mineral forms that are almost insoluble in water, and therefore not available for uptake by organisms. Most common among these forms of aluminum are various aluminosilicate minerals, aluminum clays and sesquioxides, and aluminum **phosphates**.

However, aluminum can also occur as chemical **species** that are available for biological uptake, sometimes causing toxicity. In general, bio-available aluminum is present in various water-soluble, ionic or organically complexed chemical species. Water-soluble concentrations of aluminum are largest in acidic environments, where toxicity to non-adapted plants and animals can be caused by exposure to Al^{3+} and $Al(OH)^{2+}$ ions, and in alkaline environments, where $Al(OH)_4^-$ is most prominent. Organically bound, water-soluble forms of aluminum, such as complexes with fulvic or humic acids, are much less toxic than ionic species. Aluminum is often considered to be the most toxic chemical factor in acidic soils and aquatic habitats.

Amazon basin

The Amazon basin, the region of South America drained by the Amazon River, represents the largest area of **tropical rain forest** in the world. Extending across nine different countries and covering an area of 2.3 million square mi (6 million sq. km), the Amazon basin contains the greatest abundance and diversity of life anywhere on the earth. Tremendous numbers of plant and animal **species** that occur there have yet to be discovered or properly named by scientists, as this area has only begun to be explored by competent researchers.

It is estimated that the Amazon basin contains over 20% of all higher plant species on Earth, as well as about 20% of all birdlife and 10% of all mammals. More than 2,000 known species of freshwater fishes live in the Amazon river and represent about 8% of all fishes on the planet, both freshwater and marine. This number of species is about three times the entire ichthyofauna of North America and almost ten times that of Europe. The most astonishing numbers, however, come from the river basin's insects. Every expedition to the Amazon basin yields countless new species of insects, with some individual trees in the tropical forest providing scientists with hundreds of undescribed forms. Insects represent about three-fourths of all animal life on Earth, yet biologists believe the 750,000 species that have already been scientifically named account for less than 10% of all insect life that exists.

However incredible these examples of **biodiversity** are, they may soon be destroyed as the rampant **deforestation** in the Amazon basin continues. Much of this destruction is directly attributable to human **population growth**. The number of people who have settled in the Amazonian uplands of Colombia and Ecuador has increased by 600% over the past 40 years, and this has led to the clearing of over 65% of the region's forests for agriculture.

In Brazil, up to 70% of the deforestation is tied to cattle ranching. In the past large governmental subsidies and tax incentives have encouraged this practice, which had little or no financial success and caused widespread environmental damage. Tropical soils rapidly lose their fertility, and this allows only limited annual meat production. It is often only 300 lb (136 kg) per acre, compared to over 3,000 lb (1,360 kg) per acre in North America.

Further damage to the tropical forests of the Amazon basin is linked to commercial **logging**. Although only five of the approximately 1,500 tree species of the region are extensively logged, tremendous damage is done to the surrounding forest as these are selectively removed. When loggers build roads move in heavy equipment, they may damage or destroy half of the trees in a given area.

The deforestation taking place in the Amazon basin has a wide range of environmental effects. The clearing and burning of vegetation produces **smoke** or **air pollution**, which at times has been so abundant that it is clearly visible from space. Clearing also leads to increased **soil erosion** after heavy rains, and can result in **water pollution** through **siltation** as well as increased water temperatures from increased exposure. Yet the most alarming, and definitely the most irreversible, environmental problem facing the Amazon basin is the loss of biodiversity. Through the irrevocable process of **extinction**, this may cost humanity more than the loss of species. It may cost us the loss of potential discoveries of medicines and other beneficial products derived from these species.

Ambient air

The air, external to buildings and other enclosures, found in the lower **atmosphere** over a given area, usually near the surface. **Air pollution** standards normally refer to ambient air.

Amenity value

The idea that something has worth because of the pleasant feelings it generates to those who use or view it. This value is often used in cost-benefit analysis, particularly in **shadow pricing**, to determine the worth of **natural resources** that will not be harvested for economic gain. A virgin forest will have amenity value, but its value will decrease if the forest is harvested, thus the amenity value is compared to the value of the harvested timber.

American alligator

see **Alligator, American**

American Box Turtle

Box turtles are in the Order Chelonia, Family Emydidae, and genus *Terrapene*. There are two major **species** in the United States: *carolina* (Eastern box turtle) and *ornata* (Western or ornate box turtle).

Box turtles are easily recognized by their dome-shaped upper shell (carapace) and by their lower shell (plastron) which is hinged near the front. This hinging allows them to close up tightly into the "box" when in danger (hence their name).

Box turtles are fairly small, having an adult maximum length of 4–7 in (10–18 cm). Their range is restricted to North America, with the Eastern species located over most of the eastern United States and the Western species located in the Central and Southwestern United States and into Mexico, but not as far west as California. Both species are highly variable in coloration and pattern, ranging from a uniform tan to dark brown or black, with yellow spots or streaks. They prefer a dry **habitat** such as woodlands, open brush lands, or **prairie**. They typically inhabit sandy **soil**, but are sometimes found in springs or ponds during hot weather. During the winter, they hibernate in the soil below the frost line, often as deep as 2 ft (60 cm). Their home range is usually fairly small, and they often live within areas less than 300 yd^2 (300 m^2).

Eastern box turtle. (Photograph by Robert Huffman. Fieldmark Publications. Reproduced by permission.)

Box turtles are omnivorous, feeding on living and dead insects, earthworms, slugs, fruits, berries (particularly blackberries and strawberries), leaves, and mushrooms. They have been known to ingest some mushrooms which are poisonous to humans, and there have been reports of people eating box turtles and getting sick. Other than this, box turtles are harmless to humans and are commonly collected and sold as pets (although this should be discouraged because they are now a threatened species). They can be fed raw hamburger, canned pet food, or leafy vegetables.

Box turtles normally live as long as 30–40 years. Some have been reported with a longevity of more than one hundred years, and this makes them the longest-lived land turtle. They are active from March until November and are diurnal, usually being more active in the early morning. During the afternoons they typically seek shaded areas. They breed during the spring and autumn, and the females build nests from May until July, typically in sandy soil where they dig a hole with their hind feet. The females can store sperm for several years. They typically hatch three to eight eggs that are elliptically-shaped and about 1.5 in (4 cm) in diameter. Male box turtles have a slight concavity in their plastron that aids in mounting females during copulation. All four toes on the male's hind feet are curved, which aids in holding down the posterior portion of the female's plastron during copulation. Females have flat plastrons, shorter tails, and yellow or brown eyes. Most males have bright red or pink eyes. The upper jaw of both sexes ends in a down-turned beak.

Predators of box turtles include skunks, raccoons, foxes, snakes, and other animals. Native American Indians used to eat box turtles and incorporated their shells into their ceremonies as rattles.

American Cetacean Society

The American Cetacean Society (ACS), located in San Pedro, California, is dedicated to the protection of **whales** and other cetaceans, including **dolphins** and porpoises. Principally an organization of scientists and teachers (though its membership does include students and laypeople) the ACS was founded in 1967 and claims to be the oldest whale **conservation** group in the world.

The ACS believes the best protection for whales, dolphins, and porpoises is better public awareness about "these remarkable animals and the problems they face in their increasingly threatened habitat." The organization is committed to political action through education, and much of its work has been in improving communication between marine scientists and the general public.

The ACS has developed several educational resource materials on cetaceans, making such products as the "Gray Whale Teaching Kit," "Whale Fact Pack," and "Dolphin Fact Pack," which are widely available for use in classrooms. There is a cetacean research library at the national headquarters in San Pedro, California, and the organization responds to thousands of inquiries every year. The ACS supports marine mammal research and sponsors a biennial conference on whales. It also assists in conducting whale-watching tours.

The organization also engages in more traditional and direct forms of political action. A representative in Washington, DC, monitors legislation that might affect cetaceans, attends hearings at government agencies, and participates as a member of the International **Whaling** Commission. The ACS also networks with other conservation groups. In addition, the ACS directs letter-writing campaigns, sending out "Action Alerts" to citizens and politicians. The organization is currently emphasizing the threats to marine life posed by **oil spills**, toxic wastes from industry and agriculture, and particular fishing practices (including commercial whaling).

The ACS publishes a quarterly newsletter on whale research, conservation, and education, called *WhaleNews*, and a quarterly journal of scientific articles on the same subjects, called *Whalewatcher*.

American Committee for International Conservation

The American Committee for International Conservation (ACIC), located in Washington, DC, is an association of nongovernmental organizations (NGOs) that is concerned about international conservation issues. The ACIC, founded in 1930, includes 21 member organizations. It represents conservation groups and individuals in 40 countries. While ACIC does not fund conservation research, it does promote national and international conservation research activities. Specifically, ACIC promotes conservation and preservation of **wildlife** and other **natural resources**, and encourages international research on the **ecology** of **endangered species**.

Formerly called the American Committee for International Wildlife Protection, ACIC assists **IUCN—The World Conservation Union**, an independent organization of nations, states, and NGOs, in promoting natural resource conservation. ACIC also coordinates its members' overseas research activities.

Member organizations of the ACIC include the African Wildlife Leadership Foundation, **National Wildlife Federation**, **World Wildlife Fund** (US)/RARE, Caribbean Conservation Corporation, **National Audubon Society**, **Natural Resources Defense Council**, **Nature** Conservancy, International Association of Fish and Wildlife Agencies, and **National Parks and Conservation Association**. Members also include The Conservation Foundation, International Institute for **Environment** and Development; Massachusetts Audubon Society; Chicago Zoological Society; Wildlife Preservation Trust; Wildfowl Trust; School of Natural Resources, University of Michigan; **World Resources Institute**; Global Tomorrow Coalition; and The Wildlife Society, Inc.

ACIC holds no formal meetings or conventions, nor does it publish magazines, books, or newsletters. Contact: American Committee for International Conservation, c/o

Center for Marine Conservation, 1725 DeSales Street, NW, Suite 500, Washington, DC 20036.

[*Linda Rehkopf*]

American Farmland Trust

Headquartered in Washington, DC, the American Farmland Trust (AFT) is an advocacy group for farmers and farmland. It was founded in 1980 to help reverse or at least slow the rapid decline in the number of productive acres nationwide, and it is particularly concerned with protecting land held by private farmers. The principles that motivate the AFT are perhaps best summarized in a line from William Jennings Bryan that the organization has often quoted: "Destroy our farms, and the grass will grow in the streets of every city in the country."

Over one million acres (404,700 ha) of farmland in the United States is lost each year to development, according to the AFT, and in Illinois one and a half bushels of **topsoil** are lost for every bushel of corn produced. The AFT argues that such a decline poses a serious threat to the future of the American economy. As farmers are forced to cultivate increasingly marginal land, food will become more expensive, and the United States could become a net importer of agricultural products, damaging its international economic position. The organization believes that a declining farm industry would also affect American culture, depriving the country of traditional products such as cherries, cranberries, and oranges and imperiling a sense of national identity that is still in many ways agricultural.

The AFT works closely with farmers, business people, legislators, and environmentalists "to encourage sound farming practices and wise use of land." The group directs lobbying efforts in Washington, working with legislators and policymakers and frequently testifying at congressional and public hearings on issues related to farming. In addition to mediating between farmers and state and federal government, the trust is also involved in political organizing at the grassroots level, conducting public opinion polls, contesting proposals for incinerators and toxic waste sites, and drafting model **conservation easements**. They conduct workshops and seminars across the country to discuss farming methods and **soil conservation** programs, and they worked with the State of Illinois to establish the Illinois **Sustainable Agriculture** Society. The group is currently developing kits for distribution to schoolchildren in both rural and urban areas called "Seed for the Future," which teach the benefits of agriculture and help each child grow a plant.

The AFT has a reputation for innovative and determined efforts to realize its goals, and former Secretary of Agriculture John R. Block has said that "this organization has probably done more than any other to preserve the American farm." Since its founding the trust has been instrumental in protecting nearly 30,000 acres (12,140 ha) of farmland in 19 states. In 1989, the group protected a 507-acre (205-ha) cherry farm known as the Murray Farm in Michigan, and it has helped preserve 300 acres (121 ha) of farm and **wetlands** in Virginia's Tidewater region. The AFT continues to battle **urban sprawl** in areas such as California's Central Valley and Berks County, Pennsylvania, as well as working to support farms in states such as Vermont, which are threatened not so much by development but by a poor agricultural economy. The AFT promotes a wetland policy that is fair to farmers while meeting **environment** standards, and it recently won a national award from the **Soil and Water Conservation Society** for its publication *Does Farmland Protection Pay?*

The AFT has 20,000 members and an annual budget of $3,850,000. The trust publishes a quarterly magazine called *American Farmland*, a newsletter called *Farmland Update*, and a variety of brochures and pamphlets which offer practical information on **soil erosion**, the cost of community services, and estate planning. They also distribute videos, including *The Future of America's Farmland,* which explains the sale and purchase of development rights.

American Forests

Located in Washington, DC, American Forests was founded in 1875, during the early days of the American **conservation** movement, to encourage **forest management**. Originally called the American Forestry Association, the organization was renamed in the later part of the twentieth century. The group is dedicated to promoting the wise and careful use of all **natural resources**, including **soil**, water, and **wildlife**, and it emphasizes the social and cultural importance of these resources as well as their economic value.

Although benefiting from increasing national and international concern about the **environment**, American Forests takes a balanced view on preservation, and it has worked to set a standard for the responsible harvesting and marketing of forest products. American Forests sponsors the Trees for People program, which is designed to help meet the national demand for wood and paper products by increasing the productivity of private woodlands. It provides educational

and technical information to individual forest owners, as well as making recommendations to legislators and policymakers in Washington.

To draw attention to the **greenhouse effect**, American Forests inaugurated their **Global ReLeaf** program in October 1988. Global ReLeaf is what American Forests calls "a tree-planting crusade." The message is, "Plant a tree, cool the globe," and Global ReLeaf has organized a national campaign, challenging Americans to plant millions of trees. American Forests has gained the support of government agencies and local conservation groups for this program, as well as many businesses, including such Fortune-500 companies as Texaco, McDonald's, and Ralston-Purina. The goal of the project is to plant 20 million trees by 2002. In August of 2001, there had been 19 million trees planted. Global ReLeaf also launched a cooperative effort with the **American Farmland Trust** called Farm ReLeaf, and it has also participated in the campaign to preserve Walden Woods in Massachusetts. In 1991 American Forests brought Global ReLeaf to Eastern Europe, running a workshop in Budapest, Hungary, for environmental activists from many former communist countries.

American Forests has been extensively involved in the controversy over the preservation of old-growth forests in the American Northwest. They have been working with environmentalists and representatives of the timber industry, and consistent with the history of the organization, American Forests is committed to a compromise that both sides can accept: "If we have to choose between preservation and destruction of old-growth forests as our only options, neither choice will work." American Forests supports an approach to forestry known as *New Forestry*, where the priority is no longer the quantity of wood or the number of board feet that can be removed from a site, but the vitality of the **ecosystem** the timber industry leaves behind. The organization advocates the establishment of an Old Growth Reserve in the Pacific Northwest, which would be managed by the principles of New Forestry under the supervision of a Scientific Advisory Committee.

American Forests publishes the *National Registry of Big Trees,* which celebrated its sixtieth anniversary in 2000. The registry is designed to encourage the appreciation of trees, and it includes such trees as the recently fallen Dyerville Giant, a redwood tree in California; the General Sherman, a giant sequoia in Texas; and the Wye Oak in Maryland. The group also publishes *American Forests*, a bimonthly magazine, and *Resource Hotline*, a biweekly newsletter, as well as *Urban Forests: The Magazine of Community Trees*. It presents the Annual Distinguished Service Award, the John Aston Warder Medal, and the William B. Greeley Award, among others. American Forests has over 35,000 members, a staff of 21, and a budget of $2,725,000.

American Indian Environmental Office

The American Indian Environmental Office (AIEO) was created to increase the quality of public health and environmental protection on Native American land and to expand tribal involvement in running environmental programs.

Native Americans are the second-largest landholders besides the government. Their land is often threatened by **environmental degradation** such as **strip mining**, **clear-cutting**, and toxic storage. The AIEO, with the help of the President's Federal Indian Policy (January 24, 1983), works closely with the U.S. **Environmental Protection Agency** (EPA) to prevent further degradation of the land. The AIEO has received grants from the EPA for environmental clean-up and obtained a written policy that requires the EPA to continue with the trust responsibility, a clause expressed in certain treaties that requires the EPA to notify the Tribe when performing any activities that may affect reservation lands or resources. This involves consulting with tribal governments, providing technical support, and negotiating EPA regulations to ensure that tribal facilities eventually comply.

The **pollution** of Dine Reservation land is an example of an environmental injustice that the AIEO wants to prevent in the future. The reservation has over 1,000 abandoned **uranium** mines that leak radioactive contaminants and is also home to the largest **coal** strip mine in the world. The **cancer** rate for the Dine people is 17 times the national average. To help tribes with pollution problems similar to the Dine, several offices now exist that handle specific environmental projects. They include the Office of Water, Air, Environmental Justice, Pesticides and Toxic Substances; Performance Partnership Grants; **Solid Waste** and Emergency Response; and the Tribal **Watershed** Project. Each of these offices reports to the National Indian Headquarters in Washington, DC.

At the Rio Earth Summit in 1992, the **Biodiversity** Convention was drawn up to protect the diversity of life on the planet. Many Native American groups believe that the convention also covered the protection of indigenous communities, including Native American land. In addition, the groups demand that prospecting by large companies for rare forms of life and materials on their land must stop.

Tribal Environmental Concerns

Tribal governments face both economic and social problems dealing with the demand for jobs, education, health care, and housing for tribal members. Often the reservations'

largest employer is the government, which owns the stores, gaming operations, timber mills, and manufacturing facilities. Therefore, the government must deal with the conflicting interests of protecting both economic and environmental concerns. Many tribes are becoming self-governing and manage their own **natural resources** along with claiming the reserved right to use natural resources on portions of **public land** that border their reservation. As a product of the reserved treaty rights, Native Americans can use water, fish, and hunt anytime on nearby federal land.

Robert Belcourt, Chippewa-Cree tribal member and director of the Natural Resources Department in Montana stated:

"We have to protect **nature** for our **future generations**. More of our Indian people need to get involved in natural resource management on each of our reservations. In the long run, natural resources will be our bread and butter by our developing them through tourism and **recreation** and just by the opportunity they provide for us to enjoy the outdoor world."

Belcourt has fought to destroy the negative stereotypes of **conservation** organizations that exist among Native Americans who believe, for example, that conservationists are extreme tree-huggers and insensitive to Native American culture. These stereotypes are a result of cultural differences in philosophy, perspective, and communication. To work together effectively, tribes and conservation groups need to learn about one another's cultures, and this means they must listen both at meetings and in one-on-one exchanges.

The AIEO also addresses the organizational differences that exist in tribal governments and conservation organizations. They differ greatly in terms of style, motivation, and the pressures they face. Pressures on the **Wilderness Society**, for example, include fending off attempts in Washington, D.C. to weaken key environmental laws or securing members and raising funds. Pressures on tribal governments more often are economic and social in nature and have to do with the need to provide jobs, health care, education, and housing for tribal members. Because tribal governments are often the reservations' largest employers and may own businesses like gaming operations, timber mills, manufacturing facilities, and stores, they function as both governors and leaders in economic development.

Native Americans currently occupy and control over 52 million acres (21.3 million ha) in the continental United States and 45 million more acres (18.5 million ha) in Alaska, yet this is only a small fraction of their original territories.

In the nineteenth century, many tribes were confined to reservations that were perceived to have little economic value, although valuable natural resources have subsequently been found on some of these land. Pointing to their treaties and other agreements with the federal government, many tribes assert that they have reserved rights to use natural resources on portions of public land.

In previous decades these natural resources on tribal lands were managed by the Bureau of Indian Affairs (BIA). Now many tribes are becoming self-governing and are taking control of management responsibilities within their own reservation boundaries. In addition, some tribes are pushing to take back management over some federally managed lands that were part of their original territories. For example, the Confederated Salish and Kootenai tribes of the Flathead Reservation are taking steps to assume management of the National **Bison** Range, which lies within the reservation's boundaries and is currently managed by the U.S. **Fish and Wildlife Service**.

Another issue concerns Native American rights to water. There are legal precedents that support the practice of reserved rights to water that is within or bordering a reservation. In areas where tribes fish for food, mining pollution has been a continues threat to maintaining clean water. Mining pollution is monitored, but the amount of fish that Native Americans consume is higher than the government acknowledges when setting health guidelines for their consumption. This is why the AIEO is asking that stricter regulations be imposed on mining companies. As tribes increasingly exercise their rights to use and consume water and fish, their roles in natural resource debates will increase.

Many tribes are establishing their own natural resource management and environmental quality protection programs with the help of the AIEO. Tribes have established fisheries, **wildlife**, forestry, **water quality**, **waste management**, and planning departments. Some tribes have prepared comprehensive resource management plans for their reservations while others have become active in the protection of particular **species**. The AIEO is uniting tribes in their strategy and involvement level with improving environmental protection on Native American land.

American Oceans Campaign

Located in Los Angeles, California, the American Oceans Campaign (AOC) was founded in 1987 as a political interest group dedicated primarily to the restoration, protection, and preservation of the health and vitality of coastal waters, estu-

aries, bays, **wetlands**, and oceans. More national and conservationist (rather than international and preservationist) in its focus than other groups with similar concerns, the AOC tends to view the oceans as a valuable resource whose use should be managed carefully. As current president Ted Danson puts it, the oceans must be regarded as far more than a natural preserve by environmentalists; rather, healthy oceans "sustain biological diversity, provide us with leisure and **recreation**, and contribute significantly to our nation's GNP."

The AOC's main political efforts reflect this focus. Central to the AOC's lobbying strategy is a desire to build cooperative relations and consensus among the general public, public interest groups, private sector corporations and trade groups, and public/governmental authorities around responsible management of ocean resources. The AOC is also active in grassroots public awareness campaigns through mass media and community outreach programs. This high-profile media campaign has included the production of a series of informational bulletins (Public Service Announcements) for use by local groups, as well as active involvement in the production of several documentary television series that have been broadcast on both network and public television. The AOC also has developed extensive connections with both the news and entertainment industries, frequently scheduling appearances by various celebrity supporters such as Jamie Lee Curtis, Whoopi Goldberg, Leonard Nimoy, Patrick Swayze, and Beau Bridges.

As a lobbying organization, the AOC has developed contacts with government leaders at all levels from local to national, attempting to shape and promote a variety of legislation related to clean water and oceans. It has been particularly active in lobbying for strengthening various aspects of the **Clean Water Act**, the **Safe Drinking Water Act**, the Oil **Pollution** Act, and the **Ocean Dumping Ban Act**. The AOC regularly provides consultation services, assistance in drafting legislation, and occasional expert testimony on matters concerning ocean **ecology**. Recently this has included AOC Political Director Barbara Polo's testimony before the U.S. House of Representatives Subcommittee on Fisheries, Conservation, Wildlife, and Oceans on the substance and effect of legislation concerning the protection of **coral reef** ecosystems.

Also very active at the grassroots level, AOC has organized numerous cleanup operations which both draw attention to the problems caused by **ocean dumping** and make a practical contribution to reversing the situation. Concentrating its efforts in California and the Pacific Northwest, the AOC launched its "Dive for Trash" program in 1991. As many as 1,000 divers may team up at AOC-sponsored events to recover **garbage** from the coastal waters. In cooperation with the U.S. Department of Commerce's National Maritime Sanctuary Program, the AOC is planning to add a marine environmental assessment component to this diving program, and to expand the program into Gulf and Atlantic coastal waters.

Organizationally, the AOC divides its political and lobbying activity into three separate substantive policy areas: "Critical Oceans and Coastal Habitats," which includes issues concerning estuaries, watersheds, and wetlands; "Coastal Water Pollution," which focuses on beach **water quality** and the effects of storm water **runoff**, among other issues; and "Living Resources of the Sea," which include coral reefs, fisheries, and marine mammals (especially **dolphins**). Activities in all these areas have run the gamut from public and legislative information campaigns to litigation.

The AOC has been particularly active along the California coastline and has played a central role in various programs aimed at protecting coastal wetland ecosystems from development and pollution. It has also been active in the Santa Monica Bay Restoration Project, which seeks to restore environmental balance to Santa Monica Bay. Typical of the AOC's multi-level approach, this project combines a program of public education and citizen (and celebrity) involvement with the monitoring and reduction of private-sector pollution and with the conducting of scientific studies on the impact of a various activities in the surrounding area. These activities are also combined with an attempt to raise alternative revenues to replace funds recently lost due to the reduction of both federal (**National Estuary Program**) and state government support for the conservation of coastal and marine ecosystems. In addition, the AOC has been involved in litigation against the County of Los Angeles over a plan to build flood control barriers along a section of the Los Angeles River. AOC's major concern is that these barriers will increase the amount of polluted storm water runoff being channeled into coastal waters. The AOC contends that prudent management of this storm water would be better used in recharging Southern California's scant **water resources** via storage or redirection into underground aquifers before this runoff becomes polluted.

In February of 2002, AOC teamed up with a new nonprofit ocean advocacy organization called Oceana. The focus of this partnership is the Oceans at Risk program that concentrates on the impact that wasteful fisheries have on the marine **environment**.

American Wildlands

American Wildlands (AWL) is a nonprofit wildland resource **conservation** and education organization founded in 1977. AWL is dedicated to protecting and promoting proper management of America's publicly owned wild areas and to securing **wilderness** designation for **public land** areas. The organization has played a key role in gaining legal protection for many wilderness and river areas in the U.S. interior west and in Alaska.

Founded as the American Wilderness Alliance, AWL is involved in a wide range of wilderness resource issues and programs including timber management policy reform, **habitat** corridors, rangeland management policy reform, riparian and **wetlands** restoration, and public land management policy reform. AWL promotes ecologically sustainable uses of public wildlands resources including forests, wilderness, **wildlife**, fisheries, and rivers. It pursues this mission through grassroots activism, technical support, public education, litigation, and political advocacy.

AWL maintains three offices: the central Rockies office in Lakewood, Colorado; the northern Rockies office in Bozeman, Montana; and the Sierra-Nevada office in Reno, Nevada. The organization's annual budget of $350,000 has been stable for many years, but with programs that are now being considered for addition to its agenda, that figure is expected to increase over the next few years.

The Central Rockies office in Bozeman considers its main concern timber management reform. It has launched the Timber Management Reform Policy Program, which monitors the U.S. **Forest Service** and works toward a better management of public forests. Since initiation of the program in 1986, the program includes resource specialists, a wildlife biologist, forester, water specialist, and an aquatic biologist who all report to an advisory council. A major victory of this program was stopping the sale of 4.2 million board feet (1.3 million m) of timber near the Electric Peak Wilderness Area.

Other programs coordinated by the Central Rockies office include: 1) *Corridors of Life Program* which identifies and maps wildlife corridors, land areas essential to the genetic interchange of wildlife that connect roadless lands or other wildlife habitat areas. Areas targeted are in the interior West, such as Montana, North and South Dakota, Wyoming, and Idaho; 2) The *Rangeland Management Policy Reform Program* monitors grazing allotments and files appeals as warranted. An education component teaches citizens to monitor grazing allotments and to use the appeals process within the U.S. Forest Service and **Bureau of Land Management**; 3) The *Recreation-Conservation Connection*, through newsletters and travel-adventure programs, teaches the public how to enjoy the outdoors without destroying **nature**. Six hundred travelers have participated in **ecotourism** trips through AWL.

AWL is also active internationally. The AWL/Leakey Fund has aided Dr. Richard Leakey's wildlife habitat conservation and elephant **poaching** elimination efforts in Kenya. A partnership with the Island Foundation has helped fund wildlands and river protection efforts in Patagonia, Argentina. AWL also is an active member of Canada's Tatshenshini International Coalition to protect that river and its 2.3 million acres (930,780 ha) of wilderness.

Ames test

A laboratory test developed by biochemist Bruce N. Ames to determine the possible carcinogenic nature of a substance. The Ames test involves using a particular strain of the bacteria *Salmonella typhimurium* that lacks the ability to synthesize histidine and is therefore very sensitive to **mutation**. The bacteria are inoculated into a medium deficient in histidine but containing the test compound. If the compound results in DNA damage with subsequent mutations, some of the bacteria will regain the ability to synthesize histidine and will proliferate to form colonies. The culture is evaluated on the basis of the number of mutated bacterial colonies it produced. The ability to replicate mutated colonies leads to the classification of a substance as probably carcinogenic.

The Ames test is a test for mutagenicity not carcinogenicity. However, approximately nine out of 10 mutagens are indeed carcinogenic. Therefore, a substance that can be shown to be mutagenic by being subjected to the Ames test can be reliably classified as a suspected **carcinogen** and thus recommended for further study.

Amoco Cadiz

This shipwreck in March 1978 off the Brittany coast was the first major supertanker accident since the ***Torrey Canyon*** 11 years earlier. Ironically, this spill, more than twice the size of the *Torrey Canyon*, blackened some of the same shores and was one of four substantial oil spills there since 1967. It received great scientific attention because it occurred near several renowned marine laboratories.

The cause of the wreck was a steering failure as the ship entered the English Channel off the northwest Brittany coast, and failure to act swiftly enough to correct it. During the next 12 hours, the *Amoco Cadiz* could not be extricated from the site. In fact, three separate lines from a powerful tug broke trying to remove the tanker before it drifted onto rocky shoals. Eight days later the *Amoco Cadiz* split in two.

Seabirds seemed to suffer the most from the spill, although the oil devastated invertebrates within the extensive, 20–30 ft (6-9 m) high intertidal zone. Thousands of birds died in a bird hospital described by one oil spill expert as a bird morgue. Thirty percent of France's seafood production was threatened, as well as an extensive kelp crop, harvested for **fertilizer**, **mulch**, and livestock feed. However, except on oyster farms located in inlets, most of the impact was restricted to the few months following the spill.

In an extensive journal article, Erich Grundlach and others reported studies on where the oil went and summarized the findings of biologists. Of the 223,000 metric tons released, 13.5% was incorporated within the water column, 8% went into subtidal sediments, 28% washed into the intertidal zone, 20–40% evaporated, and 4% was altered while at sea. Much research was done on chemical changes in the hydrocarbon fractions over time, including that taken up within organisms. Researchers found that during early phases, biodegradation was occurring as rapidly as evaporation.

The cleanup efforts of thousands of workers were helped by storm and wave action that removed much of the stranded oil. High energy waves maintained an adequate supply of nutrients and oxygenated water, which provided optimal conditions for biodegradation. This is important because most of the biodegradation was done by **aerobic** organisms. Except for protected inlets, much of the impact was gone three years later, but some effects were expected to last a decade.

Cleveland Amory (1917 – 1998)

American Activist and writer

Amory is known both for his series of classic social history books and his work with the **Fund for Animals**. Born in Nahant, Massachusetts, to an old Boston family, Amory attended Harvard University, where he became editor of *The Harvard Crimson*. This prompted his well-known remark, "If you have been editor of *The Harvard Crimson* in your senior year at Harvard, there is very little, in after life, for you."

Amory was hired by *The Saturday Evening Post* after graduation, becoming the youngest editor ever to join that publication. He worked as an intelligence officer in the United States Army during World War II, and in the years after the war, wrote a trilogy of social commentary books, now considered to be classics. *The Proper Bostonians* was

published to critical acclaim in 1947, followed by *The Last Resorts* (1948), and *Who Killed Society?* (1960), all of which became best sellers.

Beginning in 1952, Amory served for 11 years as social commentator on NBC's "The Today Show." The network fired him after he spoke out against cruelty to animals used in biomedical research. From 1963 to 1976, Amory served as a senior editor and columnist for *Saturday Review* magazine, while doing a daily radio commentary, entitled "Curmudgeon-at-Large." He was also chief television critic for *TV Guide*, where his biting attacks on sport **hunting** angered hunters and generated bitter but unsuccessful campaigns to have him fired.

In 1967, Amory founded The Fund for Animals "to speak for those who can't," and served as its unpaid president. Animal protection became his passion and his life's work, and he was considered one of the most outspoken and provocative advocates of animal welfare. Under his leadership, the Fund became a highly activist and controversial group, engaging in such activities as confronting hunters of **whales** and **seals**, and rescuing wild horses, burros, and goats. The Fund, and Amory in particular, are well known for their campaigns against sport **hunting and trapping**, the fur industry, abusive research on animals, and other activities and industries that engage in or encourage what they consider cruel treatment of animals.

In 1975, Amory published *ManKind? Our Incredible War on Wildlife*, using humor, sarcasm, and graphic rhetoric to attack hunters, trappers, and other exploiters of wild animals. The book was praised by *The New York Times* in a rare editorial. His next book, *AniMail*, (1976) discussed animal issues in a question-and-answer format. In 1987, he wrote *The Cat Who Came for Christmas*, a book about a stray cat he rescued from the streets of New York, which became a national best seller. This was followed in 1990 by its sequel, also a best seller, *The Cat and the Curmudgeon*. Amory had been a senior contributing editor of *Parade* magazine since 1980, where he often profiled famous personalities.

Amory died of an aneurysm at the age of 81 on October 14, 1998. He remained active right up until the end, spending the day in his office at the Fund for Animals and then passing away in his sleep later that evening. Staffers at both the Fund for Animals have vowed that Amory's work will continue, "just the way Cleveland would have wanted it."

Anaerobic

This term refers to an **environment** lacking in molecular oxygen (O_2), or to an organism, tissue, chemical reaction, or biological process that does not require oxygen. Anaerobic organisms can use a molecule other than O_2 as the terminal electron acceptor in **respiration**. These organisms can be either obligate, meaning that they cannot use O_2, or facultative, meaning that they do not require oxygen but can use it if it is available.

Organic matter **decomposition** in poorly aerated environments, including water-logged soils, septic tanks, and anaerobically-operated waste treatment facilities, produces large amounts of **methane** gas. The methane can become an atmospheric pollutant, or it may be captured and used for fuel, as in "biogas"-powered electrical generators. Anaerobic decomposition produces the notorious "swamp gases" that have been reported as unidentified flying objects (UFOs).

Anaerobic digestion

Refers to the biological degradation of either sludges or **solid waste** under **anaerobic** conditions, meaning that no oxygen is present. In the digestive process, solids are converted to noncellular end products.

In the anaerobic digestion of sludges, the goals are to reduce **sludge** volume, insure the remaining solids are chemically stable, reduce disease-causing pathogens, and enhance the effectiveness of subsequent dewatering methods, sometimes recovering **methane** as a source of energy. Anaerobic digestion is commonly used to treat sludges that contain primary sludges, such as that from the first settling basins in a **wastewater** treatment plant, because the process is capable of stabilizing the sludge with little **biomass** production, a significant benefit over **aerobic sludge digestion**, which would yield more biomass in digesting the relatively large amount of **biodegradable** matter in primary sludge.

The **microorganisms** responsible for digesting the sludges anaerobically are often classified in two groups, the **acid** formers and the methane formers. The acid formers are **microbes** that create, among others, acetic and propionic acids from the sludge. These **chemicals** generally make up about a third of the by-products initially formed based on a **chemical oxygen demand** (COD) mass balance, and some of the propionic and other acids are converted to acetic acid.

The methane formers convert the acids and by-products resulting from prior metabolic steps (e.g., alcohols, **hydrogen**, **carbon dioxide**) to methane. Often, approximately 70% of the methane formed is derived from acetic acid, about 10–15% from propionic acid.

Anaerobic digesters are designed as either standard- or high-rate units. The standard-rate digester has a solids **retention time** of 30–90 days, as opposed to 10–20 days for the high-rate systems. The volatile solids loadings of the standard- and high-rate systems are in the area of 0.5–1.6 and 1.6–6.4 $Kg/m^3/d$, respectively. The amount of sludge introduced into the standard-rate is therefore generally much less than the high-rate system. Standard-rate digestion is accomplished in single-stage units, meaning that sludge is fed into a single tank and allowed to digest and settle. High-rate units are often designed as two-stage systems in which sludge enters into a completely-mixed first stage that is mixed and heated to approximately 98°F (35°C) to speed digestion. The second-stage digester, which separates digested sludge from the overlying liquid and scum, is not heated or mixed.

With the anaerobic digestion of solid waste, the primary goal is generally to produce methane, a valuable source of fuel that can be burned to provide heat or used to power motors. There are basically three steps in the process. The first involves preparing the waste for digestion by sorting the waste and reducing its size. The second consists of constantly mixing the sludge, adding moisture, nutrients, and **pH** neutralizers while heating it to about 143°F (60°C) and digesting the waste for a week or longer. In the third step, the generated gas is collected and sometimes purified, and digested solids are disposed of. For each pound of undigested solid, about 8–12 ft^3 of gas is formed, of which about 60% is methane.

Anemia

Anemia is a medical condition in which the red cells of the blood are reduced in number or volume or are deficient in hemoglobin, their oxygen-carrying pigment. Almost 100 different varieties of anemia are known. Iron deficiency is the most common cause of anemia worldwide. Other causes of anemia include **ionizing radiation**, **lead poisoning**, vitamin B_{12} deficiency, folic **acid** deficiency, certain infections, and **pesticide** exposure. Some 350 million people worldwide—mostly women of child-bearing age—suffer from anemia.

The most noticeable symptom is pallor of the skin, mucous membranes, and nail beds. Symptoms of tissue oxygen deficiency include pulsating noises in the ear, dizziness, fainting, and shortness of breath. The treatment varies greatly depending on the cause and diagnosis, but may include supplying missing nutrients, removing toxic factors from the **environment**, improving the underlying disorder, or restoring blood volume with transfusion.

Aplastic anemia is a disease in which the bone marrow fails to produce an adequate number of blood cells. It is usually acquired by exposure to certain drugs, to **toxins** such as **benzene**, or to ionizing radiation. Aplastic anemia from **radiation exposure** is well-documented from the Chernobyl experience. Bone marrow changes typical of aplastic anemia can occur several years after the exposure to the offending agent has ceased.

Aplastic anemia can manifest itself abruptly and progress rapidly; more commonly it is insidious and chronic for several years. Symptoms include weakness and fatigue in the early stages, followed by headaches, shortness of breath, fever and a pounding heart. Usually a waxy pallor and hemorrhages occur in the mucous membranes and skin. **Resistance** to infection is lowered and becomes the major cause of death. While spontaneous recovery occurs occasionally, the treatment of choice for severe cases is bone marrow transplantation.

Marie Curie, who discovered the element radium and did early research into **radioactivity**, died in 1934 of aplastic anemia, most likely caused by her exposure to ionizing radiation.

While lead poisoning, which leads to anemia, is usually associated with occupational exposure, toxic amounts of lead can leach from imported ceramic dishes. Other environmental sources of lead exposure include old paint or paint dust, and drinking water pumped through lead pipes or lead-soldered pipes.

Cigarette smoke is known to cause an increase in the level of hemoglobin in smokers, which leads to an underestimation of anemia in smokers. Studies suggest that **carbon monoxide** (a by-product of smoking) chemically binds to hemoglobin, causing a significant elevation of hemoglobin values. Compensation values developed for smokers can now detect possible anemia.

Animal cancer tests

Cancer causes more loss of life-years than any other disease in the United States. At first reading, this statement seems to be in error. Does not cardiovascular disease cause more deaths? The answer to that rhetorical question is "yes." However, many deaths from heart attack and stroke occur in the elderly. The loss of life-years of an 85 year old person (whose life expectancy at the time of his/her birth was between 55 and 60) is, of course, zero. However, the loss of life-years of a child of 10 who dies of a pediatric **leukemia** is between 65 to 70 years. This comparison of youth with the elderly is not meant in any way to demean the *value* that reasonable people place on the lives of the elderly. Rather, the comparison is made to emphasize the great loss of life due to malignant tumors.

The chemical causation of cancer is not a simple process. Many, perhaps most, chemical carcinogens do not in their usual condition have the potency to cause cancer. The non-cancer causing form of the chemical is called a "procarcinogen." Procarcinogens are frequently complex organic compounds that the human body attempts to dispose of when ingested. Hepatic enzymes chemically change the procarcinogen in several steps to yield a chemical that is more easily excreted. The chemical changes result in modification of the procarcinogen (with no cancer forming ability) to the ultimate **carcinogen** (with cancer causing competence). Ultimate carcinogens have been shown to have a great affinity for DNA, RNA, and cellular proteins, and it is the interaction of the ultimate carcinogen with the cell macromolecules that causes cancer. It is unfortunate indeed that one cannot look at the chemical structure of a potential carcinogen and predict whether or not it will cause cancer. There is no computer program that will predict what hepatic enzymes will do to procarcinogens and how the metabolized end product(s) will interact with cells.

Great strides have been made in the development of chemotherapeutic agents designed to cure cancer. The drugs have significant efficacy with certain cancers (these include but are not limited to pediatric acute lymphocytic leukemia, choriocarcinoma, Hodgkin's disease, and testicular cancer), and some treated patients attain a normal life span. While this development is heartening, the cancers listed are, for the most part, relatively infrequent. More common cancers such as colorectal carcinoma, lung cancer, breast cancer, and ovarian cancer remain intractable with regard to treatment.

These several reasons are why animal testing is used in cancer research. The majority of Americans support the effort of the biomedical community to use animals to identify potential carcinogens with the hope that such knowledge will lead to a reduction of cancer prevalence. Similarly, they support efforts to develop more effective chemotherapy. Animals are used under terms of the Animal Welfare Act of 1966 and its several amendments. The act designates that the U. S. Department of Agriculture is responsible for the humane care and handling of warm-blooded and other animals used for biomedical research. The act also calls for inspection of research facilities to insure that adequate food, housing, and care are provided. It is the belief of many that the constraints of the current law have enhanced the quality of biomedical research. Poorly maintained animals do not provide quality research. The law also has enhanced the care of animals used in cancer research.

Animal Legal Defense Fund

Originally established in 1979 as Attorneys for Animal Rights, this organization changed its name to Animal Legal Defense Fund (ALDF) in 1984, and is known as "the law firm of the **animal rights** movement." Their motto is "we may be the only lawyers on earth whose clients are all innocent." ALDF contends that animals have a fundamental right to legal protection against abuse and exploitation. Over 350 attorneys work for ALDF, and the organization has more than 50,000 supporting members who help the cause of animal rights by writing letters and signing petitions for legislative action. The members are also strongly encouraged to work for animal rights at the local level.

ALDF's work is carried out in many places including research laboratories, large cities, small towns, and the wild. ALDF attorneys try to stop the use of animals in research experiments, and continue to fight for expanded enforcement of the Animal Welfare Act. ALDF also offers legal assistance to humane societies and city prosecutors to help in the enforcement of anti-cruelty laws and the exposure of veterinary malpractice. The organization attempts to protect wild animals from exploitation by working to place controls on trappers and sport hunters. In California, ALDF successfully stopped the **hunting** of mountain lions and black bears. ALDF is also active internationally bringing legal action against elephant poachers as well as against animal dealers who traffic in **endangered species**.

ALDF's clear goals and swift action have resulted in many court victories. In 1992 alone, the organization won cases involving cruelty to **dolphins**, dogs, horses, birds, and cats. It has also blocked the importation of over 70,000 monkeys from Bangladesh for research purposes, and has filed suit against the National Marine Fisheries Services to stop the illegal gray market in dolphins and other marine mammals. ALDF also publishes a quarterly magazine, *The Animals' Advocate*.

Animal rights

Recent concern about the way humans treat animals has spawned a powerful social and political movement driven by the conviction that humans and certain animals are similar in morally significant ways, and that these similarities oblige humans to extend to those animals serious moral consideration, including rights. Though animal welfare movements, concerned primarily with humane treatment of pets, date back to the 1800s, modern animal rights activism has developed primarily out of concern about the use and treatment of domesticated animals in agriculture and in medical, scientific, and industrial research. The rapid growth in membership of animal rights organizations testifies to the increasing momentum of this movement. The leading animal rights group today, **People for the Ethical Treatment of Animals** (PETA), was founded in 1980 with 100 individuals; today, it has over 300,000 members. The animal rights activist movement has closely followed and used the work of modern philosophers who seek to establish a firm logical foundation for the extension of moral considerability beyond the human community into the animal community.

The nature of animals and appropriate relations between humans and animals have occupied Western thinkers for millennia. Traditional Western views, both religious and philosophical, have tended to deny that humans have any moral obligations to nonhumans. The rise of Christianity and its doctrine of personal immortality, which implies a qualitative gulf between humans and animals, contributed significantly to the dominant Western paradigm. When seventeenth century philosopher René Descartes declared animals mere biological machines, the perceived gap between humans and nonhuman animals reached its widest point. Jeremy Bentham, the father of ethical utilitarianism, challenged this view and fostered a widespread anticruelty movement and exerted powerful force in shaping our legal and moral codes. Its modern legacy, the animal welfare movement, is reformist in that it continues to accept the legitimacy of sacrificing animal interests for human benefit, provided animals are spared any suffering which can conveniently and economically be avoided.

In contrast to the conservatively reformist platform of animal welfare crusaders, a new radical movement began in the late 1970s. This movement, variously referred to as animal liberation or animal rights, seeks to put an end to the routine sacrifice of animal interests for human benefit. In

Animal rights activists dressed as monkeys in prison suits block the entrance to the Department of Health and Human Services in Washington, DC, in protest of the use of animals in laboratory research. (Corbis-Bettmann. Reproduced by permission.)

seeking to redefine the issue as one of rights, some animal protectionists organized around the well-articulated and widely disseminated utilitarian perspective of Australian philosopher **Peter Singer**. In his 1975 classic *Animal Liberation*, Singer argued that because some animals can experience pleasure and pain, they deserve our moral consideration. While not actually a rights position, Singer's work nevertheless uses the language of rights and was among the first to abandon welfarism and to propose a new ethic of moral considerability for all sentient creatures.

To assume that humans are inevitably superior to other **species** simply by virtue of their species membership is an injustice which Singer terms **speciesism**, an injustice parallel to racism and sexism.

Singer does not claim all animal lives to be of equal worth, nor that all sentient beings should be treated identically. In some cases, human interests may outweigh those of nonhumans, and Singer's utilitarian calculus would allow us to engage in practices which require the use of animals in spite of their pain, where those practices can be shown to produce an overall balance of pleasure over suffering.

Some animal advocates thus reject **utilitarianism** on the grounds that it allows the continuation of morally abhorrent practices. Lawyer Christopher Stone and philosophers Joel Feinberg and **Tom Regan** have focused on developing cogent arguments in support of rights for certain animals. Regan's 1983 book *The Case For Animal Rights* developed an absolutist position which criticized and broke from utilitarianism. It is Regan's arguments, not reformism or the pragmatic principle of utility, which have come to dominate the rhetoric of the animal rights crusade.

The question of which animals possess rights then arises. Regan asserts it is those who, like us, are subjects experiencing their own lives. By "experiencing" Regan means conscious creatures aware of their **environment** and with goals, desires, emotions, and a sense of their own identity. These characteristics give an individual inherent value, and this value entitles the bearer to certain inalienable rights,

especially the right to be treated as an end in itself, and never merely as a means to human ends.

The environmental community has not embraced animal rights; in fact, the two groups have often been at odds. A rights approach focused exclusively on animals does not cover all the entities such as ecosystems that many environmentalists feel ought to be considered morally. Yet a rights approach that would satisfy environmentalists by encompassing both living and nonliving entities may render the concept of rights philosophically and practically meaningless. Regan accuses environmentalists of environmental fascism, insofar as they advocate the protection of species and ecosystems at the expense of individual animals. Most animal rightists advocate the protection of ecosystems only as necessary to protect individual animals, and assign no more value to the individual members of a highly **endangered species** than to those of a common or domesticated species. Thus, because of its focus on the individual, animal rights can offer no realistic plan for managing natural systems or for protecting **ecosystem health**, and may at times hinder the efforts of resource managers to effectively address these issues.

For most animal activists, the practical implications of the rights view are clear and uncompromising. The rights view holds that all animal research, factory farming, and commercial or sport **hunting and trapping** should be abolished. This change of moral status necessitates a fundamental change in contemporary Western moral attitudes towards animals, for it requires humans to treat animals as inherently valuable beings with lives and interests independent of human needs and wants. While this change is not likely to occur in the near future, the efforts of animal rights advocates may ensure that wholesale slaughter of these creatures for unnecessary reasons that is no longer routinely the case, and that when such sacrifice is found to be necessary, it is accompanied by moral deliberation.

Animal waste

Animal wastes are commonly considered the excreted materials from live animals. However, under certain production conditions, the waste may also include straw, hay, wood shavings, or other sources of organic debris. It has been estimated that there may be as much as 2 billion tons of animal wastes produced in the United States annually. Application of excreta to **soil** brings benefits such as improved soil **tilth**, increased water-holding capacity, and some plant nutrients. Concentrated forms of excreta or high application rates to soils without proper management may lead to high salt concentrations in the soil and cause serious on- or off-site **pollution**.

Animal Welfare Institute

Founded in 1951, the Animal Welfare Institute (AWI) is a non-profit organization that works to educate the public and to secure needed action to protect animals. AWI is a highly respected, influential, and effective group that works with Congress, the public, the news media, government officials, and the **conservation** community on animal protection programs and projects. Its major goals include improving the treatment of laboratory animals and a reduction in their use; eliminating cruel methods of **trapping wildlife**; saving **species** from **extinction**; preventing painful experiments on animals in schools and encouraging humane science teaching; improving shipping conditions for animals in transit; banning the importation of **parrots** and other exotic wild birds for the pet industry; and improving the conditions under which farm animals are kept, confined, transported, and slaughtered.

In 1971 AWI launched the **Save the Whales** Campaign to help protect **whales**. The organization provides speakers and experts for conferences and meetings around the world, including Congressional hearings and international treaty and commission meetings. Each year, the institute awards its prestigious **Albert Schweitzer** Medal to an individual for outstanding achievement in the advancement of animal welfare. Its publications include *The AWI Quarterly*; books such as *Animals and Their Legal Rights*; *Facts about Furs*; and *The Endangered Species Handbook*; booklets, brochures, and other educational materials, which are distributed to schools, teachers, scientists, government officials, humane societies, libraries, and veterinarians.

AWI works closely with its associate organization, The Society for Animal Protective Legislation (SAPL), a lobbying group based in Washington, D.C. Founded in 1955, SAPL devotes its efforts to supporting legislation to protect animals, often mobilizing its 14,000 "correspondents" in letter-writing campaigns to members of Congress.

SAPL has been responsible for the passage of more animal protection laws than any other organization in the country, and perhaps the world, and it has been instrumental in securing the enactment of 14 federal laws.

Major federal legislation which SAPL has promoted includes the first federal Humane Slaughter Act in 1958 and its strengthening in 1978; the 1959 Wild Horse Act; the 1966 Laboratory Animal Welfare Act and its strengthening in 1970, 1976, 1985, and 1990; the 1969 **Endangered Species Act** and its strengthening in 1973; a 1970 measure banning the crippling or "soring" of Tennessee Walking Horses; measures passed in 1971 prohibiting **hunting** from aircraft, protecting wild horses, and resolutions calling for a moratorium on commercial **whaling**; the 1972 Marine Mammal Protection Act; negotiation of the 1973 Convention on International Trade in **Endangered Species** of **Fauna** and **Flora** (CITES); the 1979 Packwood-Magnuson Amendment protecting whales and other ocean creatures; the 1981 strengthening of the Lacey Act to restrict the importation of illegal wildlife; the 1990 Pet Theft Act; and, in 1992, The Wild Bird Conservation Act, protecting parrots and other exotic wild birds; the International Dolphin Conservation Act, restricting the killing of **dolphins** by tuna fishermen; and the Driftnet Fishery Conservation Act, protecting whales, sea birds, and other ocean life from being caught and killed in huge, 30-mi-long (48-km-long) nets.

Major goals of SAPL include enacting legislation to end the use of cruel steel-jaw leg-hold traps and to secure proper enforcement, funding, administration, and reauthorization of existing animal protection laws. Both AWI and SAPL have long been headed by their chief volunteer, Christine Stevens, a prominent Washington, D.C. humanitarian and community leader.

Antarctic Treaty (1961)

The Antarctic Treaty, signed in 1961, established an international administrative system for the continent. The impetus for the treaty was the International Geophysical Year, 1957–1958, which had brought scientists from many nations together to study **Antarctica**. The political situation in Antarctica was complex at the time, with seven nations having made sometimes overlapping territorial claims to the continent: Argentina, **Australia**, Chile, France, New Zealand, Norway, and the United Kingdom. Several other nations, most notably the former USSR and the United States, had been active in Antarctic exploration and research and were concerned with how the continent would be administered.

Negotiations on the treaty began in June 1958 with Belgium, Japan, and South Africa joining the original nine countries. The treaty was signed in December 1959 and took effect in June 1961. It begins by "recognizing that it is in the interest of all mankind that Antarctica shall continue forever to be used exclusively for peaceful purposes." The key to the treaty was the nations' agreement to disagree on territorial claims. Signatories of the treaty are not required to renounce existing claims, nations without claims shall have an equal voice as those with claims, and no new claims or claim enlargements can take place while the treaty is in force. This agreement defused the most controversial and complex issue regarding Antarctica, and in an unorthodox way. Among the other major provisions of the treaty are: the continent will be demilitarized; nuclear explosions and the storage of nuclear wastes are prohibited; the right of unilateral inspection of all facilities on the continent to ensure that the provisions of the treaty are being honored is guaranteed; and scientific research can continue throughout the continent.

The treaty runs indefinitely and can be amended, but only by the unanimous consent of the signatory nations. Provisions were also included for other nations to become parties to the treaty. These additional nations can either be "acceding parties," which do not conduct significant research activities but agree to abide by the terms of the treaty, or "consultative parties," which have acceded to the treaty and undertake substantial scientific research on the continent. Twelve nations have joined the original 12 in becoming consultative parties: Brazil, China, Finland, Germany, India, Italy, Peru, Poland, South Korea, Spain, Sweden, and Uruguay.

Under the auspices of the treaty, the Convention on the Conservation of Antarctic Marine Living Resources was adopted in 1982. This regulatory regime is an effort to protect the Antarctic marine **ecosystem** from severe damage due to **overfishing**. Following this convention, negotiations began on an agreement for the management of Antarctic mineral resources. The Convention on the Regulation of Antarctic Mineral Resource Activities was concluded in June 1988, but in 1989 Australia and France rejected the convention, urging that Antarctica be declared an international

wilderness closed to mineral development. In 1991 the Protocol on Environmental Protection, which included a 50-year ban on mining, was drafted. At first the United States refused to endorse this protocol, but it eventually joined the other treaty parties in signing the new convention in October 1991.

Books

Shapley, D. *The Seventh Continent: Antarctica in a Resource Age*. Baltimore: Johns Hopkins University Press for Resources for the Future, 1985.

Antarctica

The earth's fifth largest continent, centered asymmetrically around the South Pole. Ninety-eight percent of this land mass, which covers approximately 5.4 million mi^2 (13.8 million km^2), is covered by snow and ice sheets to an average depth of 1.25 mi (2 km). This continent receives very little precipitation, less than 5 in (12 cm) annually, and the world's coldest temperature was recorded here, at -128°F (-89°C). Exposed shorelines and inland mountain tops support life only in the form of **lichens**, two **species** of flowering plants, and several insect species. In sharp contrast, the ocean surrounding the Antarctic continent is one of the world's richest marine habitats. Cold water rich in oxygen and nutrients supports teeming populations of **phytoplankton** and shrimp-like Antarctica **krill**, the food source for the region's legendary numbers of **whales**, **seals**, penguins, and fish. During the nineteenth and early twentieth century, whalers and sealers severely depleted Antarctica's marine mammal populations. In recent decades the whale and seal populations have begun to recover, but interest has grown in new resources, especially oil, minerals, fish, and tourism.

The Antarctic's functional limit is a band of turbulent ocean currents and high winds that circle the continent at about 60 degrees south latitude. This ring is known as the Antarctic convergence zone. Ocean turbulence in this zone creates a barrier marked by sharp differences in **salinity** and water temperature. Antarctic marine habitats, including the limit of krill populations, are bounded by the convergence.

Since 1961 the **Antarctic Treaty** has formed a framework for international cooperation and compromise in the use of Antarctica and its resources. The treaty reserves the Antarctic continent for peaceful scientific research and bans all military activities. Nuclear explosions and **radioactive waste** are also banned, and the treaty neither recognizes nor establishes territorial claims in Antarctica. However, neither does the treaty deny pre-1961 claims, of which seven exist. Furthermore, some signatories to the treaty, including the United States, reserve the right to make claims at a later date. At present the United States has no territorial claims, but it does have several permanent stations, including one at the South Pole. Questions of territorial control could become significant if oil and mineral resources were to become economically recoverable. The primary resources currently exploited are fin fish and krill fisheries. Interest in oil and mineral resources has risen in recent decades, most notably during the 1973 "oil crisis." The expense and difficulty of extraction and **transportation** has so far made exploitation uneconomical, however.

Human activity has brought an array of environmental dangers to Antarctica. Oil and mineral extraction could seriously threaten marine **habitat** and onshore penguin and seal breeding grounds. A growing and largely uncontrolled fishing industry may be depleting both fish and krill populations in Antarctic waters. The parable of the **Tragedy of the Commons** seems ominously appropriate to Antarctica fisheries, which have already nearly eliminated many whale, seal, and penguin species. **Solid waste** and **oil spills** associated with research stations and with tourism pose an additional threat. Although Antarctica remains free of "permanent settlement," 40 year-round scientific research stations are maintained on the continent. The population of these bases numbers nearly 4,000. In 1989 the Antarctic had its first oil spill when an Argentine supply ship, carrying 81 tourists and 170,000 gal (643,500 l) of diesel fuel, ran aground. Spilled fuel destroyed a nearby breeding colony of Adele penguins (*Pygoscelis adeliae*). With more than 3,000 cruise ships visiting annually, more spills seem inevitable. Tourists themselves present a further threat to penguins and seals. Visitors have been accused of disturbing breeding colonies, thus endangering the survival of young penguins and seals.

Antarctica Project

The Antarctica Project, founded in 1982, is an organization designed to protect **Antarctica** and educate the public, government, and international groups about its current and

future status. The group monitors activities that affect the Antarctic region, conducts policy research and analysis in both national and international arenas, and maintains an impressive library of books, articles, and documents about Antarctica. It is also a member of the Antarctic and Southern Ocean Coalition (ASOC), which has 230 member organizations in 49 countries.

In 1988, ASOC received a limited observer status to the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR). So far, the observer status continues to be renewed, providing ASOC with a way to monitor CCAMLR and to present proposals. In 1989, the Antarctica Project served as an expert adviser to the U.S. Office of Technology Assessment on its study and report of the Minerals Convention. The group prepared a study paper outlining the need for a comprehensive environmental protection convention. Later, a **conservation** strategy on Antarctica was developed with **IUCN—The World Conservation Union**.

Besides continuing the work it has already begun, the Antarctica Project has several goals for the future. One calls for the designation of Antarctica as a world park. Another focuses on developing a bilateral plan to pump out the oil and salvage the *Bahia Parasio*, a ship which sank in early 1989 near the U.S. Palmer Station. Early estimated salvage costs ran at $50 million. One of the more recent projects is the Southern Ocean Fisheries Campaign. This campaign targets the illegal fishing taking place in the Southern Ocean which is depleting the Chilean sea bass population. The catch phrase of this movement is "Take a Pass on Chilean Sea Bass."

Three to four times a year, The Antarctica Project publishes *ECO*, an international publication which covers current political topics concerning the **Antarctic Treaty** System (provided free to members). Other publications include briefing materials, critiques, books, slide shows, videos, and posters for educational and advocacy purposes.

Anthrax

Anthrax is a bacterial infection caused by *Bacillus anthracis*. It usually affects cloven-hoofed animals, such as cattle, sheep, and goats, but it can occasionally spread to humans. Anthrax is almost always fatal in animals, but it can be successfully treated in humans if antibiotics are given soon after exposure. In humans, anthrax is usually contracted when spores are inhaled or come in contact with the skin. It is also possible for people to become infected by eating the meat of contaminated animals. Anthrax, a deadly disease in **nature**, gained worldwide attention in 2001 after it was used as a **bioterrorism** agent in the United States. Until the 2001 attack, only 18 cases of anthrax had been reported in the United States in the previous 100 years.

Anthrax occurs naturally. The first reports of the disease date from around 1500 B.C., when it is believed to have been the cause of the fifth Egyptian **plague** described in the Bible. Robert Koch first identified the anthrax bacterium in 1876 and Louis Pasteur developed an anthrax vaccine for sheep and cattle in 1881. Anthrax bacteria are found in nature in South and Central America, southern and eastern Europe, Asia, Africa, the Caribbean, and the Middle East. Anthrax cases in the United States are rare, probably due to widespread vaccination of animals and the standard procedure of disinfecting animal products such as cowhide and wool. Reported cases occur most often in Texas, Louisiana, Mississippi, Oklahoma, and South Dakota.

Anthrax spores can remain dormant (inactive) for years in **soil** and on animal hides, wool, hair, and bones. There are three forms of the disease, each named for its means of transmission: cutaneous (through the skin), inhalation (through the lungs), and intestinal (caused by eating anthrax-contaminated meat). Symptoms appear within several weeks of exposure and vary depending on how the disease was contracted.

Cutaneous anthrax is the mildest form of the disease. Initial symptoms include itchy bumps, similar to insect bites. Within two days, the bumps become inflamed and a blister forms. The centers of the blisters are black due to dying tissue. Other symptoms include shaking, fever, and chills. In most cases, cutaneous anthrax can be treated with antibiotics such as penicillin. Intestinal anthrax symptoms include stomach and intestinal inflammation and pain, nausea, vomiting, loss of appetite, and fever, all becoming progressively more severe. Once the symptoms worsen, antibiotics are less effective, and the disease is usually fatal.

Inhalation anthrax is the form of the disease that occurred during the bioterrorism attacks of October and November 2001 in the eastern United States. Five people died after being exposed to anthrax through contaminated mail. At least 17 other people contracted the disease but survived.

Anthrax lesion on the shoulder of a patient. (NMSB/Custom Medical Stock Photo. Reproduced by permission.)

One or more terrorists sent media organizations in Florida and New York envelopes containing anthrax. Anthrax-contaminated letters also were sent to the Washington, D.C. offices of two senators. Federal agents were still investigating the incidents as of May 2002 but admitted they had no leads in the case. Initial symptoms of inhalation anthrax are flu-like, but breathing becomes progressively more difficult. Inhalation anthrax can be treated successfully if antibiotics are given before symptoms develop. Once symptoms develop, the disease is usually fatal.

The only natural outbreak of anthrax among people in the United States occurred in Manchester, New Hampshire, in 1957. Nine workers in a textile mill that processed wool and goat hair contracted the disease, five with inhalation anthrax and four with cutaneous anthrax. Four of the five people with inhalation anthrax died. By coincidence, workers at the mill were participating in a study of an experimental anthrax vaccine. No workers who had been vaccinated contracted the disease.

Following this outbreak, the study was stopped, all workers at the mill were vaccinated, and vaccination became a condition of employment. After that, no mill workers contracted anthrax. The mill closed in 1968. However, in 1966 a man who worked across the street from the mill died from inhalation anthrax. He is believed to have contracted it from anthrax spores carried from the mill by the wind. The United States **Food and Drug Administration** approved the anthrax vaccine in 1970. It is used primarily for military personnel and some health care workers. During the 2001 outbreak, thousands of postal workers were offered the vaccine after anthrax spores from contaminated letters were found at several post office buildings.

The largest outbreak worldwide of anthrax in humans occurred in the former Soviet Union in 1979, when anthrax spores released from a military laboratory infected 77 people, 69 of whom died. Anthrax is an attractive weapon to bioterrorists. It is easy to transport and is highly lethal. The World Health Organization (WHO) estimates that 110 lb (50 kg) of anthrax spores released upwind of a large city would kill tens of thousands of people, with thousands of others ill and requiring medical treatment.

The Geneva Convention, which established a code of conduct for war, outlawed the use of anthrax as a weapon in 1925. However, Japan developed anthrax weapons in the 1930s and used them against civilian populations during World War II. During the 1980s, Iraq mass produced anthrax as a weapon.

Anthropocentrism

see **Environmental ethics**

Anthropogenic

Refers to changes in the natural world due to the activities of people. Such changes may be positive or negative. For example, anthropogenic changes in soils can occur due to plowing, fertilizing, using the **soil** for construction, or long continued manure additions. When manure is added to soils, the change is considered beneficial, but when soils are compacted for use as parking lots, the change is considered negative. Other examples of anthropogenic effects on the **environment** include **oil spills**, **acid rain**, **logging** of old-growth forests, creation of **wetlands**, preservation of **endangered species**, among others.

Antibiotic resistance

Antibiotics are drugs principally derived from naturally occurring **fungi** and **microorganisms** that kill bacteria and can cure patients with bacterial diseases. Before the advent of antibiotics in the 1940s, many common diseases were lethal or incurable. Tuberculosis, pneumonia, scarlet fever, staph and strep infections, typhoid fever, gonorrhea, and syphilis were all dreaded diseases until the development of penicillin and other antibiotics in the middle of the twentieth century. Yet almost as soon as antibiotics came into common use, scientists noticed that some strains of disease-causing bacteria developed **resistance** to the antibiotic used most often against it. People infected with an antibiotic-resistant bacteria must be treated with different antibiotics, often more potent and toxic than the commonly used drug. In some cases, bacteria may be resistant to several antibiotics. Tuberculosis, once the leading killer in the United States at the beginning of the nineteenth century, seemed defeated with the introduction of streptomycin and PAS in the 1940s and early 1950s. But tuberculosis resurged in the United States and worldwide in the 1990s as people came down with antibiotic-resistant strains of the disease. Bacteria that cause salmonella, a food-borne illness, have become increasingly resistant to antibiotics by the early twenty-first century, as have the bacteria that commonly cause early childhood ear infections. Misuse and overuse of antibiotics contribute to the rise of resistant strains.

Bacteria can become resistant to antibiotics relatively quickly. Bacteria multiply rapidly, producing a new generation in as little as a half hour. So evolutionary pressures can produce bacteria with new characteristics in very little time. When a person takes an antibiotic, the drug will typically kill almost all the bacteria it is designed to destroy, plus other beneficial bacteria. Some small percentage of the disease bacteria, maybe as little as 1%, may have a natural ability to resist the antibiotic. So a small number of resistant bacteria may survive drug treatment. When these resistant bacteria are all that are left, they are free to multiply, passing the resistance to their offspring. Physicians warn people to take the full prescribed course of antibiotics even if symptoms of the disease disappear in a day or two. This is to limit the danger of resistant bacteria flourishing. Bacteria can also develop resistance by contact with other **species** of bacteria that are resistant. Neighboring bacteria can pass genetic material back and forth by swapping bits of DNA called plasmids. If bacteria that normally live on the skin and bacteria that live in the intestine should come into contact with each other, they may make a plasmid exchange, and spread antibiotic resistant qualities. Antibiotic-resistant bacteria are often resistant to a whole class of antibiotics, that is, a group of antibiotics that function in a similar way. People afflicted with a resistant strain of bacteria must be treated with a different class of antibiotics.

Antibiotic resistance was evident in the 1940s, though penicillin had only become available in 1941. By 1946, one London hospital reported that 14% of patients with staph infections had penicillin-resistant strains, and that number rose precipitously over the next decade. In 1943 scientists brought out streptomycin, a new antibiotic that fought tuberculosis (penicillin was found not to work against that disease). But streptomycin-resistant strains of tuberculosis developed rapidly, and other drugs had to be found. In 1959, physicians in Japan found a virulent strain of dysentery that was resistant to four different classes of antibiotic. Some troubling cases of antibiotic resistance have been isolated incidents. But by the 1990s it was clear that antibiotic resistance was a widespread and growing problem. A few cases around the world in 1999 found deadly bacteria resistant to vancomycin, a powerful antibiotic described as a drug of last resort because it is only used when all other antibiotics fail. By this time, scientists in many countries were deeply alarmed about the growing public health threat of antibiotic resistance. A study done by the Mayo clinic and reported in 2001 claimed that deaths from infectious diseases had risen 58% between 1980 and 1992, a rising toll attributed in part to antibiotic resistance. The U.S. **Centers for Disease Control and Prevention** (CDC) claimed in 2001 that antibiotic resistance had spread to "virtually all important human pathogens treatable with antibiotics."

Antibiotic resistance makes treatment of infected patients difficult. The sexually transmitted disease gonorrhea was easily cured with a single dose of penicillin in the middle of the twentieth century. By the 1970s, penicillin-resistant strains of the disease had become prevalent in Asia, and migrated from there to the rest of the world. Penicillin was no longer used to treat gonorrhea in the United States after 1987. Standard treatment was then a dose of either of two classes of antibiotics, fluoroquinolones, or cephalosporins. By the late 1990s, strains of gonorrhea resistant to fluoroquinolones had been detected in Asia. The resistant strains showed up in California in 2001. The California CDC soon recommended not using fluoroquinolones to treat gonorrhea, fearing that use of these drugs would actually strengthen the antibiotic resistance. If patients were only partially cured by fluoroquinolones, yet some infection lingered, they could pass the resistant strain to others. And the resistance could become stronger as only the most resistant bacteria survived exposure to the drug. So public health officials and doctors were left with cephalosporins to treat gonorrhea, more costly drugs with more risk of side effects.

Overuse of antibiotics contributes to antibiotic resistance. The number of antibiotic prescriptions for children rose almost 50% in the United States between 1980 and

1992. Children and the elderly are the most likely to receive antibiotic prescriptions. By 1998 the CDC estimated that approximately half the 100 million prescriptions for antibiotics issued by doctor's offices in the United States annually were unnecessary. Antibiotics work only against bacterial diseases, and are useless against viral infections. Yet physicians frequently prescribe antibiotics for coughs and colds. An article on the problem in *American Family Physician* found that most doctors understood the inappropriateness of their prescriptions, yet feared that patients were unsatisfied with their care unless they received a drug. The CDC launched various state and national initiatives to educate both doctors and their patients about overuse of antibiotics. Other groups took on specific diseases. For example, an association of pediatricians publicized the danger of over prescribing for childhood ear infections in 2001. The common ailment was known to be treatable without antibiotics, but many doctors continued to give antibiotics anyway. By 2001, almost one-third of children in daycare who had ear infections had an antibiotic-resistant form, according to a survey conducted by the National Association of Child Care Professionals (NACCP). The NACCP hoped to convince both pediatricians and parents to use antibiotics only when necessary. The president of the American Medical Association spoke out in 2001 about the number of prescriptions for ciprofloxacin (Cipro) given out in the wake of the mail attacks of inhalation **anthrax**. Tens of thousands of people received prescriptions for Cipro in October 2001, putting them at risk for developing pools of Cipro-resistant bacteria in their bodies. Most bacteria live in the body without causing harm, but can make people ill if they build up to certain levels, or if a person's immune system is weakened. People carrying Cipro-resistant bacteria could potentially come down with a resistant form of pneumonia or some other bacterial illness later in life.

People are also exposed to antibiotics through meat and other food. About half the antibiotics used in the United States go to farm animals, and some are also sprayed on fruits and vegetables. Some farm animals are given antibiotics to cure a specific disease. But other antibiotics are given as preventives, and to promote growth. Animals living in crowded and dirty conditions are more susceptible to disease, and the preventive use of antibiotics keeps such animals healthier than they would otherwise be. The antibiotics prescribed by veterinarians are similar or the same as drugs used in humans. Farm animals in the United States are routinely fed penicillin, amoxicillin, tetracycline, ampicillin, erythromycin, and neomycin, among others, and studies have shown that antibiotic resistance is common in contaminated meat and eggs. One study conducted by the **Food and Drug Administration** (FDA) and the University of Maryland and reported in 2001 found 20% of ground meat samples taken from several urban supermarkets contained salmonella bacteria. Over 80% of the salmonella bacteria sampled was resistant to at least one antibiotic and over half was resistant to at least three antibiotics. Salmonella bacteria is killed when meat is cooked properly, and most cases of salmonella disease get better without treatment. But for the small percent of cases of more serious infection, multiple antibiotic resistance could make treatment very difficult. A food-borne *E. coli* bacteria was found in 2001 to be causing urinary tract infections which were resistant to the standard antibiotic treatment. Twenty percent of the urinary tract infections studied were resistant to Bactrim, meaning that in most cases physicians would be advised to treat with a stronger antibiotic with more side effects.

Antibiotics in preventive doses or for growth promotion of farm animals were banned by the **European Union** in 1998. Many groups in the United States concerned with antibiotic resistance recommend the United States follow suit. The plan released by the CDC, the Food and Drug Administration (FDA) and the National Institutes of Health (NIH) in 2001 to combat antibiotic resistance called for increased monitoring of antibiotic use in agriculture and in human health. The plan also called for public education on the risks of overuse and improper use of antibiotics, and for more research in combating drug-resistant diseases. The FDA continued to investigate links between agricultural use of antibiotics and human health.

Aquaculture

Aquaculture is the husbandry or rearing of aquatic organisms under controlled or semi-controlled conditions. Stated another way, it is the art of cultivating natural plants and animals in water for human consumption or use. It can be considered aquatic agriculture, or as some people wish to call it, underwater agriculture. It is sometimes incorrectly termed aquiculture. Aquaculture involves production in both fresh and salt water. **Mariculture** is aquaculture in saline (**brackish** and marine) water. **Hydroponics** is the raising of aquatic plants in water. Organisms that are grown in aquaculture include fish, shellfish (crustaceans such as crawfish and shrimp, and mollusks such as oysters and clams), algae, and aquatic plants. More people are eating seafood for their added health benefit. Not only can these organisms be raised for human consumption, but they can also be reared for the lucrative baitfish, health food, aquarium, and home garden-pond industries.

Aquaculture dates back more than 3,500 years ago when carp were spawned and reared in China. There have also been records of aquaculture practices being performed in Egypt and Japan nearly that long ago. Mariculture is thought to have been brought to Hawaii about 1,500 years ago. Modern aquaculture finds its roots in the 1960s in the culturing of catfish in the United States and **salmon** in Europe.

There are two general methods used in aquaculture, extensive and intensive. Extensive aquaculture involves the production of low densities of organisms. For example, fingerling fish can be raised in ponds where they feed on the natural foods such as **phytoplankton** and **zooplankton**, and the matured fish are harvested at the end of the growing season. These ponds can also be fertilized to enhance the food chain, thus increasing fish or shellfish production. Typically, several hundred to several thousand pounds of fish are raised per acre annually. Intensive practices utilize much higher densities of organisms. This requires better **water quality**, which necessitates circulation, oxygenation, added commercial foods, and biological **filters** (with bacteria) to remove toxic wastes. These systems can produce more than one million lb of fish per acre (45,000/ha). Intensive aquaculture often utilizes tanks to grow the fish or shellfish, either indoor or outdoor. The water can be recirculated as long as toxic wastes such as ammonia are removed. Some processors run the **effluent** from the fish tanks through greenhouses with plants raised hydroponically to remove these **chemicals**. In this way, added revenue is gained. Some aquaculture operations raise only one type of organism (called **monoculture**) while others grow several **species** together (termed polyculture). An example of polyculture would be growing tilapia and catfish together.

About 86% of the world's aquaculture production (about 22 million tons in 1993) comes from Asia. China is the leading producer nation, with most of their production coming from carp, and secondarily shrimp. India is the second largest producer nation, followed by Japan, Taiwan, and the Philippines. For example, 1991 shrimp production in China reached nearly 250,000 tons. (Note: One English ton equals approximately one metric ton, so they can be thought of as equivalents). Only Taiwan exceeded this with 350,000 tons of shrimp produced. Ecuador produced 100,000 tons. In contrast, total shrimp production for the United States was only 1,600 tons. Salmon is another major fish produced by aquaculture, with most coming from Norway. Nearly 300,000 tons were produced in 1990. Great Britain, Canada, Chile, and Iceland are also major producers of farm-raised salmon. Other important aquaculture species and some of the countries where they are raised include: tilapia (Caribbean countries, Egypt, India, Israel, the Philippines); milkfish (the Philippines); Nile perch (Egypt); sea bass and sea bream (Egypt, Israel); mullet (Egypt, India, Israel); dolphin fish (also known as mahi-mahi; Egypt); grass and silver carp (Israel); halibut and other flatfishes (France, Norway); prawns (Caribbean countries, Israel, the Philippines); mussels and oysters (the Philippines); crabs (India); seaweeds (India, Japan); *Spirulina* (a blue-green algae; India); and many other examples.

Although people in the United States consume less fish and shellfish than people in other parts of the world, each year we spend billions of dollars importing edible fish. Total production from aquaculture in the United States in 1991 was about 540,000 tons, which earned about $750

million. This comprises only about 3% of the world's total aquaculture production. Domestically, catfish is our major aquaculture species ($200 million per year in 1991). Trout (primarily raised in Idaho) is the number two species raised in aquaculture and accounts for a $55 million per year industry. Shrimp, hybrid-striped bass, and tilapia are other species commonly raised in the United States. Of the 16,000 tons of crawfish (more appropriately called crayfish) collected in 1990 in the United States, about 60% came from aquaculture ponds.

In 1986 the U.S. Congress placed aquaculture under the jurisdiction of the **U.S. Department of Agriculture** appropriated $3 million to establish four regional aquaculture centers. These centers are located at the University of Washington, Southeastern Massachusetts University, Mississippi State University, and a Center for Tropical and Subtropical Aquaculture jointly administered by the University of Hawaii and the Oceanic Institute. The following year Congress created a fifth center at Michigan State University. The mandate for these centers was, and still is, to promote aquaculture in their region and to solve some of the problems facing this industry. More recent legislation has created mariculture research centers under the Sea Grant Program within the Department of Commerce.

Aquaculture is an appealing industry because it can help supplement what is caught in natural fisheries and what is produced through agriculture. This has tremendous implications in terms of the growing future dilemma with human over-population, decreased fisheries captured from the oceans, and stabilized agriculture production. Aquaculture is a growing industry in the world, which not only translates into more food, but also more revenue and jobs. This fulfills the old Chinese proverb that you can give a person a fish and feed them for a day, or you can teach a person to fish (or do aquaculture) and feed them for a lifetime.

It is particularly important to look at aquaculture development in third-world countries where protein sources are scarce. Since many of these countries lie in equatorial regions, tilapia (also called St. Peter's fish because they are the likely fish caught by the disciples in the Sea of Galilee) are one of the best prospects to grow because of their tolerance of high temperatures and poor water quality (i.e., high ammonia levels). They are also omnivorous filter feeders and thrive on blue-green algae. One alternative to the **deforestation** of our precious rain forests might be to encourage indigenous people to construct earthen ponds and raise tilapia on the fringes of the forests, thus producing not only a protein source, but also a **cash crop**. An advantage of aquaculture over agriculture is that fish can be grown in ponds overlying **soil** that may be toxic to plants (for example, with high concentrations of sulphur, **aluminum**, or salt). In addition, aquaculture species can often be held longer if there is a glut on the market, thus allowing more flexible selling times. Despite these positive attributes, there are serious problems involved in aquaculture. These include release of waste into the water (adversely affecting water quality); spread of diseases and **parasites** through concentrated growing conditions; disfavorable taste through chemicals like geosmin in the water being taken up by the fish (termed "off-flavor" in catfish); release of hybrid strains into the natural population which can result in mixed genetics with natural populations; obstruction of the aesthetics along coastlines; and overproduction, which can result in depressed market prices. For example, both the catfish and salmon industries experienced a tremendous drop in their market prices due to overproduction in 1990 and 1991.

Aquaculture seems to have a bright future as long as we address some of the above-mentioned problems. One example of an enterprising solution to one of these problems is that of releasing wrasse (marine parasite-feeding fish) into aquaculture tanks and cages to remove fish lice from salmon. This not only solves the problem of parasites, but also eliminates the need to add chemicals to the water that kill parasites, stress the fish, and pollute the **environment**. The same pitfalls that have plagued agriculture must be avoided in aquaculture. A key concern is that of sustainability—concern for the culture environment and non-crop organisms in measuring the success of the aquaculture industry (discussed in the June 1996 issue of *World Aquaculture*). There is no need for agriculture farmers to feel threatened by aquaculture; on the contrary, it seems that these two areas can actually be brought together, particularly with small local farms in underdeveloped countries supplementing their terrestrial crops with aquatic production. This has already been done quite well in Norway, which has more than 700 fish farms in a country with only 4.2 million people. Aquaculture is evolving from an art, with trial-and-error learning, to more of a science with ongoing research. Countries such as Japan, the United States, Israel, and Norway are developing new technology to bring this field to higher levels. Recent predictions suggest that aquaculture will be able to meet at least 40% of the global demand for fish and shellfish over the next 15 years if current trends prevail. Government, academic institutions, and industry must work hand-in-hand to see that these predictions come to fruition with minimal environmental damage.

Aquarium trade

International trade in live fish and other marine **species** for international aquarium hobby market. Most fish, corals, and other marine aquarium species traded internationally are collected live from tropical and subtropical coral reefs, especially in the Philippines, Indonesia, and other Asian countries. Nearly half the world aquarium fish market is in the United States. Although the capture and marketing of live reef species provides a significant income source in remote communities, international trade has alarmed conservationists and environmentalists because of harmful collecting methods. A majority of live tropical fish are captured with sodium cyanide (NaCN), a highly toxic and inexpensive powdered poison. Divers use squirt bottles containing a cyanide solution or drop cyanide tablets into reef crevices where fish hide. The poison stuns the fish, making them easy to capture, and the fish usually recover after a few minutes. Fish are transferred to holding tanks on ships and then transported to international wholesalers. From 70–90% of fish captured with cyanide die later, however, due to damage to the liver, stomach, and other tissues. Another problem common in salt water aquaria is "sudden death syndrome," when fish inexplicably die soon after they are introduced to the aquarium. Some researchers attribute the syndrome to cyanide, which is stored in tissues during transport. Fish are often not fed during storage, but when they begin to eat in their new aquarium, or if they undergo even mild shock, the cyanide is released into the blood stream and kills the fish. Although solid figures are impossible to establish, estimates of the proportion of tropical live fish caught with cyanide are 75% or higher worldwide, and 90% in some countries.

The reefs where fish are captured fare as badly as the fish: one study found all cyanide-treated corals dead within three months after treatment. Coral reefs also suffer physical damage as divers break off chunks of coral to retrieve stunned fish. Despite harm to reefs and high fish **mortality** rates, cyanide is considered the most cost effective method to capture popular species such as angel fish and trigger fish.

Peter Rubec, a researcher with the International Marinelife Alliance, reports that an exporter operating from Manila initiated the export of marine fish from the Philippines in 1957. With almost 2,200 fish species, the Philippines has the highest reef fish diversity in the world, including 200 species that are commonly exported for the marine pet fish industry. In 1986 Filipino reefs provided as much as 80% of the world's tropical marine fish, a number that fell only to 70% by 1997. From 1970–1980 exports rose from 1,863,000 lb (845,000 kg) of live fish packed in water to 4.41 million lb (2 million kg) worth $2 billion dollars. Since then export numbers have fallen in the Philippines, as stocks have thinned and the trade has diversified to other countries, but in 1986 the country's marine tropical fish trade was worth $10 million dollars. Worldwide the value of aquarium fish was $100 million dollars, plus corals and other supplies.

Cyanide fishing was first introduced in the Philippines in about 1962. The technique has since spread to Indonesia, New Guinea, and other regions where live fish are caught. Cyanide has since been banned in the Philippines and Indonesia, but enforcement is difficult because fishing vessels are dispersed, often in hard-to-reach sections of remote islands. Despite legal bans, an estimated 375,000 lb (170,000 kg) of cyanide is still used each year in the Philippines. Cyanide fishing boats have even exploited established marine preserves and parks, such as Indonesia's Take Bone Atoll. Furthermore, as enforcement mechanisms develop, cyanide fishing can quickly spread to other countries, where laws are still weak or lacking.

The greatest problems of the live reef fish trade result from its mobility. The frontier of cyanide fishing has moved steadily through Southeast Asia to tropical Pacific islands and even across the Indian Ocean to the Seychelles and Tanzania, as fertile reefs have disappeared and as governments caught on to their fishing practices and began to impose laws restricting the use of cyanide and explosives. Since the market is international and lucrative, it does not matter where the fish are caught. Furthermore, fish exporters succeed best if they continually explore new, unexploited reefs where more unusual and exotic fish can be found. The migratory nature of the industry makes it easy for fishing vessels to move on as soon as a country begins to enact or enforce limits on their activities.

Starting in 1984 international **conservation** groups have worked to introduce net fishing as a less harmful fishing alternative that still allows divers to retain their income from live fish. To catch fish with nets, divers may use a stick to drive fish from their hiding places in the reef and then trap the fish with a fine mesh net. Reports indicate that long-term survival rates of net-caught fish may be as high as 90%, compared to as little as 10% among cyanide-caught fish. In Hawaii and **Australia**, where legal controls are more effective than in Southeast Asia, nets are used routinely. Although the aquarium industry has provided little aid in the effort to increase net-fishing, local communities in the Philippines

and Indonesia, with the aid of international conservationist organizations, have worked to encourage net fishing. Increased local control of reef fisheries is also important in helping communities to control cyanide fishing in their nearby reefs. Local communities that have depended on reefs and their fish for generations understand that sustainable use is both possible and essential for their own survival, so they often have a greater incentive to prevent reef damage than either state governments or transient fishing enterprises. In an effort to help coastal villages help themselves, the government of the Philippines has recently granted villagers greater rights to patrol and control nearby fishing areas.

Another step toward the control of cyanide fishing is the development of cyanide detection techniques that allow wholesalers to determine whether fish are tainted with residual cyanide. Simply by sampling the water a fish is carried in, the test can detect if the fish is releasing cyanide from its tissues or metabolizing cyanide. Ideally this test could help control illegal and harmful fish trade, but thus far it is not widely used. Attempts have also begun to establish cyanide-free certification, but this has been slow to take effect because the market is dispersed and there are many different exporters.

Coastal villages also suffer from reef damage. Most coastal communities in **coral reef** regions have traditionally relied on the rich fishery supported by the reef as a principal protein and food source. As reefs suffer, fisheries deteriorate. Some researchers estimate that just 1,300 ft (400 m) of healthy reef the can support 800 people, while the same amount of damaged reef can support only a quarter that many people. Other ecological benefits also disappear as reefs deteriorate, since healthy coral reefs perform critical water clarification functions. Corals, along with sea anemones and other life forms they shelter, filter floating organic matter from the water column, cycling it into the food chain that supports fish, crustaceans, birds, and humans. By breaking ocean waves offshore, healthy and intact corals also control beach **erosion** and reduce storm surges, the unusually large waves and tides associated with storms and high winds.

Divers collecting the fish suffer as well. Exposure to cyanide and inadequate or unsafe breathing hoses are common problems. In addition divers must search deeper waters as more accessible fish are depleted. In 1993, 40 divers in a single small village were reported to have been injured and 10 killed by the bends, which results from rapid changes of pressure as divers rise from deep water.

Unfortunately there has been relatively little breeding of tropical fish in aquaria, at least in part because these fish often have specialized **habitat** needs and life style requirements that are difficult to produce under controlled or domestic conditions. In addition the aquarium trade is specialized and limited in volume, and gearing up to produce fish can be an expensive undertaking for which a reliable market must be assured. Equally unfortunate is the fact that American and European dealers in aquarium products tend to be elusive about the details of where their fish came from and how they were caught. If pet shops do not mention the source, many aquarium owners are able to ignore the implications of the fish trade they are participating in.

In addition to aquarium fishing, cyanide has now been introduced to the live food-fish market, especially in Asia, where live fish are an expensive delicacy. The live food/fish trade, centered in China and Hong Kong, is estimated to exceed $1 billion per year. The Hong Kong cyanide fleet alone has hundreds of vessels, each employing up to 25 divers to catch fish with cyanide for the Chinese and Hong Kong restaurant market.

Another harmful fishing technique is blast fishing—releasing a small bomb that breaks up coral masses in which fish hide. A single explosive might destroy corals in a circle from 10–33 ft (3–10 m) wide. The fish, briefly stunned by the blast, are easily retrieved from the rubble. Half the countries in the South Pacific have seen coral damage from blasting, including Guam, Indonesia, Malaysia, and Thailand. The technique has also spread to Africa, where it is used in Tanzania and other countries bordering the Indian Ocean.

Some environmentalists stress that simply eliminating the live fish trade is not an adequate solution. Because live fish are so lucrative, much more valuable than the same weight in dead fish, fishermen may be able to produce a better income with fewer fish when they catch live fish. Steering the fish capture methods to a safer alternative, especially the use of nets, could do more to save reef communities than eliminating the trade altogether.

[*Mary Ann Cunningham*]

Aquatic chemistry

Water can exist in various forms within the **environment**, including: (1) liquid water of oceans, lakes and ponds, rivers and streams, **soil** interstices, and underground aquifers; (2)

solid water of glacial ice and more-ephemeral snow, rime, and frost; and (3) vapor water of cloud, fog, and the general **atmosphere**. More than 97% of the total quantity of water in the hydrosphere occurs in the oceans, while about 2% is glacial ice, and less than 1% is **groundwater**. Only about 0.01% occurs in freshwater lakes, and the quantities in other compartments are even smaller.

Each compartment of water in the hydrosphere has its own characteristic chemistry. Seawater has a relatively large concentration of inorganic solutes (about 3.5%), dominated by the ions chloride (1.94%), sodium (1.08%), sulfate (0.27%), magnesium (0.13%), calcium (0.041%), potassium (0.049%), and bicarbonate (0.014%).

Surface waters such as lakes, ponds, rivers, and streams are highly variable in their chemical composition. Saline and soda lakes of **arid** regions have total salt concentrations that can substantially exceed that of seawater. Lakes such as Great Salt Lake in Utah and the Dead Sea in Israel can have salt concentrations that exceed 25%. The shores of such lakes are caked with a crystalline rime of evaporate minerals, which are sometimes mined for industrial use.

The most chemically dilute surface waters are lakes in watersheds with hard, slowly **weathering** bedrock and soils. Such lakes can have total salt concentrations of less than 0.001%. For example, Beaverskin Lake in Nova Scotia has very clear, dilute water that is chemically dominated by chloride, sodium, and sulfate, in concentrations of two-thirds of the norm for surface water or less, with only traces of calcium, usually most abundant, and no silica. A nearby body of water, Big Red Lake, has a similarly dilute concentration of inorganic ions but, because it receives **drainage** from a bog, its chemistry also includes a large concentration of dissolved organic **carbon**, mainly comprised of humic/fulvic acids that stain the water a dark brown and greatly inhibit the penetration of sunlight.

The water of precipitation is considerably more dilute than that of surface waters, with concentrations of sulfate, calcium, and magnesium of one-fortieth to one-hundredth of surface water levels, but adding small amounts of nitrate and ammonium. Chloride and sodium concentrations depend on proximity to salt water. For example, precipitation at a remote site in Nova Scotia, only 31 mi (50 km) from the Atlantic Ocean, will have six to 10 times as much sodium and chloride as a similarly remote location in northern Ontario.

Acid rain is associated with the presence of relatively large concentrations of sulfate and nitrate in precipitation water. If the negative electrical charges of the sulfate and nitrate anions cannot be counterbalanced by positive charges of the cations sodium, calcium, magnesium, and ammonium, then **hydrogen** ions go into solution, making the water acidic. **Hubbard Brook Experimental Forest**, New Hampshire, within an **airshed** of industrial, **automobile**, and residential emissions from the northeastern United States and eastern Canada, receives a substantially acidic precipitation, with an average **pH** of about 4.1. At Hubbard Brook, sulfate and nitrate together contribute 87% of the anion-equivalents in precipitation. Because cations other than the hydrogen **ion** can only neutralize about 29% of those anion charges, hydrogen ions must go into solution, making the precipitation acidic.

Fogwaters can have much larger chemical concentrations, mostly because the inorganic **chemicals** in fogwater droplets are less diluted by water than in rain and snow. For example, fogwater on Mount Moosilauke, New Hampshire, has average sulfate and nitrate concentrations about nine times more than in rainfall there, with ammonium eight times more, sodium seven times more, and potassium and the hydrogen ion three times more.

The above descriptions deal with chemicals present in relatively large concentrations in water. Often, however, chemicals that are present in much smaller concentrations can be of great environmental importance.

For example, in freshwaters phosphate is the **nutrient** that most frequently limits the productivity of plants, and therefore, of the aquatic **ecosystem**. If the average concentration of phosphate in lake water is less than about 10 μg/l, then the algae productivity will be very small, and the lake is classified as **oligotrophic**. Lakes with phosphate concentrations ranging from about 10–35 μg/l are mesotrophic, those with 35–100 μg/l are eutrophic, and those with more than 100 μ/l are very productive, and very green, hypertrophic waterbodies. In a few exceptional cases, the productivity of freshwater may be limited by **nitrogen**, silica, or carbon, and sometimes by unusual micronutrients. For example, the productivity of **phytoplankton** in Castle Lake, California, has been shown to be limited by the availability of the trace metal, molybdenum.

Sometimes, chemicals present in trace concentrations in water can be toxic to plants and animals, causing substantial ecological changes. An important characteristic of acidic waters is their ability to solubilize **aluminum** from minerals, producing ionic aluminum. In non-acidic waters, ionic aluminum is generally present in minute quantities, but in very acidic waters when pH is less than 2, attainable by **acid mine drainage**, soluble-aluminum concentrations can rise drastically. Although some aquatic biota are physiologically tolerant of these aluminum ions, other **species**, such as fish, suffer toxicity and may disappear from acidified waterbodies. Many aquatic species cannot tolerate even small quantities of ionic aluminum. Many ecologists believe that aluminum ions are responsible for most of the toxicity of acidic waters and also of acidic soils.

Some chemicals can be toxic to aquatic biota even when present in ultra trace concentrations. Many species within the class of chemicals known as **chlorinated hydrocarbons** are insoluble in water but are soluble in biological lipids such as animal fats. These chemicals often remain in the environment because they are not easily metabolized by **microorganisms** or degraded by **ultraviolet radiation** or other inorganic processes. Examples of chlorinated **hydrocarbons** are the insecticides DDT, DDD, dieldrin, and methoxychlor, the class of dielectric fluids known as PCBs, and the chlorinated **dioxin**, TCDD.

These chemicals are so dangerous because they collect in biological tissues, and accumulate progressively as organisms age. They also accumulate into especially large concentrations in organisms at the top of the ecosystem's **food chain/web**. In some cases, older individuals of top predator species have been found to have very large concentrations of chlorinated hydrocarbons in their fatty tissues. The toxicity caused to raptorial birds and other predators as a result of their accumulated doses of DDT, PCBs, and other chlorinated hydrocarbons is a well-recognized environmental problem.

Water pollution can also be caused by the presence of hydrocarbons. Accidental spills of **petroleum** from disabled tankers are the highest profiled causes of oil **pollution**, but smaller spills from tankers disposing of oily bilge waters and chronic discharges from refineries and **urban runoff** are also significant sources of oil pollution. Hydrocarbons can also be present naturally, as a result of the release of chemicals synthesized by algae or during **decomposition** processes in **anaerobic sediment**. In a few places, there are natural seepages from near-surface petroleum reservoirs, as occurs in the vicinity of Santa Barbara, California. In general, the typical, naturally-occurring concentration of hydrocarbons in seawater is quite small. Beneath a surface slick of spilled petroleum, however, the concentration of soluble hydrocarbons can be multiplied several times, sufficient to cause toxicity to some biota. This dissolved fraction does not include the concentration of finely suspended droplets of petroleum, which can become incorporated into an oil-in-water emulsion toxic to organisms that become coated with it. In general, within the very complex mix of hydrocarbons found in petroleum, the smallest molecules are the most soluble in water.

Aquatic microbiology

Aquatic microbiology is the science that deals with microscopic living organisms in fresh or salt water systems. While aquatic microbiology can encompass all **microorganisms**, including microscopic plants and animals, it more commonly refers to the study of bacteria, viruses, and **fungi** and their relation to other organisms in the aquatic **environment**.

Bacteria are quite diverse in **nature**. The scientific classification of bacteria divides them into 19 major groups based on their shape, cell structure, staining properties (used in the laboratory for identification), and metabolic functions. Bacteria occur in many sizes as well ranging from 0.1 micrometer to greater than 500 micrometers. Some are motile and have flagella, which are tail-like structures used for movement.

Although **soil** is the most common **habitat** of fungi, they are also found in aquatic environments. Aquatic fungi are collectively called *water molds* or *aquatic Phycomycetes*. They are found on the surface of decaying plant and animal matter in ponds and streams. Some fungi are parasitic and prey on algae and protozoa.

Viruses are the smallest group of microorganisms and usually are viewed only with the aid of an electron microscope. They are disease-causing organisms that are very different than bacteria, fungi, and other cellular life-forms. Viruses are infectious **nucleic acid** enclosed within a coat of protein. They penetrate host cells and use the nucleic **acid** of other cells to replicate.

Bacteria, viruses, and fungi are widely distributed throughout aquatic environments. They can be found in fresh water rivers, lakes, and streams, in the surface waters and sediments of the world's oceans, and even in hot springs. They have even been found supporting diverse communities at **hydrothermal vents** in the depths of the oceans.

Microorganisms living in these diverse environments must deal with a wide range of physical conditions, and each has specific adaptations to live in the particular place it calls home. For example, some have adapted to live in fresh waters with very low **salinity**, while others live in the saltiest parts of the ocean. Some must deal with the harsh cold of arctic waters, while those in hot springs are subjected to intense heat. In addition, aquatic microorganisms can be found living in environments where there are extremes in other physical parameters such as pressure, sunlight, organic substances, dissolved gases, and water clarity.

Aquatic microorganisms obtain nutrition in a variety of ways. For example, some bacteria living near the surface of either fresh or marine waters, where there is often abundant sunlight, are able to produce their own food through the process of **photosynthesis**. Bacteria living at hydrothermal vents on the ocean floor where there is no sunlight can

produce their own food through a process known as **chemosynthesis**, which depends on preformed organic **carbon** as an energy source. Many other microorganisms are not able to produce their own food. Rather, they obtain necessary nutrition from the breakdown of organic matter such as dead organisms.

Aquatic microorganisms play a vital role in the cycling of nutrients within their environment, and thus are a crucial part of the **food chain/web**. Many microorganisms obtain their nutrition by breaking down organic matter in dead plants and animals. As a result of this process of decay, nutrients are released in a form usable by plants. These aquatic microorganisms are especially important in the cycling of the nutrients **nitrogen**, **phosphorus**, and carbon. Without this **recycling**, plants would have few, if any, organic nutrients to use for growth.

In addition to breaking down organic matter and recycling it into a form of nutrients that plants can use, many of the microorganisms become food themselves. There are many types of animals that graze on bacteria and fungi. For example, some deposit-feeding marine worms ingest sediments and digest numerous bacteria and fungi found there, later expelling the indigestible sediments. Therefore, these microorganisms are intimate members of the food web in at least two ways.

Humans have taken advantage of the role these microorganisms play in **nutrient** cycles. At **sewage treatment** plants, microscopic bacteria are cultured and then used to break down human wastes. However, in addition to the beneficial uses of some aquatic microorganisms, others may cause problems for people because they are pathogens, which can cause serious diseases. For example, viruses such as *Salmonella typhi*, *S. paratyphi*, and the Norwalk **virus** are found in water contaminated by sewage can cause illness. Fecal coliform (*E. coli*) bacteria and Enterococcus bacteria are two types of microorganisms that are used to indicate the presence of disease causing microorganisms in aquatic environments.

[*Marci L. Bortman*]

Aquatic toxicology

Aquatic toxicology is the study of the adverse effects of **toxins** and their activities on aquatic ecosystems. Aquatic toxicologists assess the condition of aquatic systems, monitor trends in conditions over time, diagnose the cause of damaged systems, guide efforts to correct damage, and predict the consequences of proposed human actions so the ecological consequences of those actions can be considered before damage occurs. Aquatic toxicologists study adverse effects at different spatial, temporal, and organizational scales. Because aquatic systems contain thousands of **species**, each of these species can respond to toxicants in many ways, and interactions between these species can be affected.

Consequently, a virtually unlimited number of responses could be produced by **chemicals**. Scientists study effects as specific as a physiological response of an important fish species or as inclusive as the biological diversity of a large river basin. Generally, attention is first focused on responses that are considered important either socially or biologically. For example, if a societal goal is to have fishable waters, responses to toxicants of game fishes and the organisms they depend on would be of interest.

The two most common tools used in aquatic toxicology are the field survey and the toxicity test. A field survey characterizes the indigenous **biological community** of an aquatic system or **watershed**. Chemistry, geology, and **land use** are also essential components of field surveys. Often, the characteristics of the community are compared to other similar systems that are in good condition. Field surveys provide the best evidence of the existing condition of natural systems. However, when damaged communities and chemical contamination co-occur, it is difficult to establish a cause-and-effect relationship using the field survey alone. Toxicity tests can help to make this connection. The toxicity test excises some replicable piece of the system of interest, perhaps fish or microbial communities of lakes, and exposes it to a chemical in a controlled, randomized, and replicable manner. The most common aquatic toxicity test data provide information about the short-term survival of fish exposed to one chemical. Such tests demonstrate whether a set of chemical conditions can cause a specified response. They also provide information about what concentrations of the chemical are of concern. Toxicity tests can suggest a threshold chemical concentration below which the adverse effect is not expected to occur; they can also present an index of relative toxicity used to rank the toxicity of two chemicals. By using information from the field survey and toxicity tests, along with other tools such as tests on the fate of chemicals released into aquatic systems, aquatic toxicologists can develop models predicting the effects of proposed actions.

The most important challenge to aquatic toxicology will be to develop methods that support sustainable use of the aquatic and other ecosystems. Sustainable use is intended to ensure that those now living do not deprive **future generations** of the essential **natural resources** necessary to maintain a quality lifestyle. Achieving the goal of sustainable use will require aquatic toxicologists to have a much longer temporal perspective than we now have. Additionally, in a more crowded and increasingly affluent world, cumulative effects will become extremely important.

[*John Cairns Jr.*]

Aquatic weed control

A simple definition of an aquatic weed is a plant that grows (usually too densely) in an area such that it hinders the usefulness or enjoyment of that area. Some common examples of aquatic plants that can become weeds are the water milfoils, ribbon weeds, and pondweeds. They may grow in ponds, lakes, streams, rivers, navigation channels, and seashores, and the growth may be due to a variety of factors such as excess nutrients in the water or the introduction of rapidly-growing **exotic species**. The problems caused by aquatic weeds are many, ranging from unsightly growth and nuisance odors to clogging of waterways, damage to shipping and underwater equipment, and impairment of **water quality**.

It is difficult and usually unnecessary to eliminate weeds completely from a lake or stream. Therefore, aquatic weed control programs usually focus on controlling and maintaining the prevalence of the weeds at an acceptable level. The methods used in weed control may include one or a combination of the following: physical removal, mechanical removal, **habitat** manipulation, biological controls, and chemical controls.

Physical removal of weeds involves cutting, pulling, or raking weeds by hand. It is time-consuming and labor-intensive and is most suitable for small areas or for locations that cannot be reached by machinery. Mechanical removal is accomplished by specialized harvesting machinery equipped with toothed blades and cutting bars to cut the vegetation, collect it, and haul it away. It is suitable for off-shore weed removal or to supplement chemical control. Repeated harvesting is usually necessary and often the harvesting blades may be limited in the depth or distance that they can reach. Inadvertent dispersal of plant fragments may also occur and lead to weed establishment in new areas. Operation of the harvesters may disturb fish habitat.

Habitat manipulation involves a variety of innovative techniques to discourage the establishment and growth of aquatic weeds. Bottom liners of plastic sheeting placed on lake bottoms can prevent the establishment of rooted plants. Artificial shading can discourage the growth of shade-intolerant **species**. Drawdown of the water level can be used to eliminate some species by desiccation. **Dredging** to remove accumulated sediments and organic matter can also delay colonization by new plants.

Biological control methods generally involve the introduction of weed-eating fish, insects, competing plant species or weed pathogens into an area of high weed growth. While there are individual success stories (for example, stocking lakes with grass carp), it is difficult to predict the long-term effects of the **introduced species** on the native species and **ecology** and therefore, biological controls should be used with caution.

Chemical control methods consist of the application of herbicides that may be either **systemic** or contact in **nature**. Systemic herbicides are taken up into the plant and cause plant death by disrupting its **metabolism** in various ways. Contact herbicides only kill the directly exposed portions of the plant, such as the leaves. While herbicides are convenient and easy to use, they must be selected and used with care at the appropriate times and in the correct quantities. Sometimes, they may also kill non-target plant species and in some cases, toxic residues from the degrading **herbicide** may be ingested and transferred up the food chain.

Aquifer

Natural zones below the surface that yield water in sufficient quantities to be economically important for industrial, agricultural, or domestic purposes. Aquifers can occur in a variety of geologic materials, ranging from glacial-deposited outwash to sedimentary beds of limestone and sandstone, and fractured zones in dense igneous rocks. Composition and characteristics are almost infinite in their variety.

Aquifers can be confined or unconfined. Unconfined aquifers are those where direct contact can be made with the **atmosphere**, while confined aquifers are separated from the atmosphere by impermeable materials. Confined aquifers are also artesian aquifers. Though originally artesian was a term applied to water in an aquifer under sufficient pressure to produce flowing **wells**, the term is now generally applied to all confined situations.

Aquifer depletion

An **aquifer** is water-saturated geological layer that easily releases water to **wells** or springs for use as a water supply. Also called ground water reservoirs or water-bearing formations, aquifers are created and replenished when excess precipitation (rain and snowfall) is held in the **soil**. This water is not released through **runoff** nor is removed by the surface flows of rivers or streams. Plants have used what they need (**transpiration**) and little is evaporated from non-living surfaces, such as soil. The remaining excess water slowly percolates downward through the soil and through the air spaces and cracks of the surface **overburden** of rocks into the bedrock. As water collects in this saturated area or **recharge**

zone, it becomes **groundwater**. The uppermost level of the saturated area is called the **water table**.

Groundwater is especially abundant in humid areas where the overburden is relatively thick and the bedrock is porous or fractured, particularly in areas of sedimentary rocks such as sandstone or limestone. Aquifers are extremely valuable **natural resources** in regions where lakes and rivers are not abundant. Groundwater is usually accessed by drilling a well and then pumping the water to the surface.

In less-moist environments, however, the quantity of precipitation available to recharge groundwater is much smaller. Slowly recharging aquifers in **arid** environments are easily depleted if their groundwater is used rapidly by humans. In some cases, groundwater sources may exist in water-bearing geologic areas that make pumping nearly impossible. Moreover, increased **irrigation** use has led to heavy pumping that is draining aquifers and lowering water tables around the world. Aquifer depletion is a growing problem as world populations increase and the need for increased food supplies.

Large, rapidly recharging aquifers underlying humid landscapes can sustain a high rate of pumping of their groundwater. As such, they can be sustainably managed as a renewable resource. Aquifers that recharge very slowly, however, are essentially filled with old, so-called "fossil" water that has accumulated over thousands or more years. This kind of aquifer has little capability of recharging as the groundwater is used because the groundwater is depleted so rapidly for human use. Therefore, slowly recharging aquifers are essentially non- renewable resources, whose reserves are mined by excessive use.

In 1999, the **Worldwatch Institute** reported that water tables were falling on every continent in the world, mainly because of excessive human consumption. Groundwater in India, in particular, is being pumped at double the rate of the aquifer's ability to recharge from rainfall. The aquifer under the North China Plain is seeing its water table fall at 5 feet (1.5 meters) a year.

In the United Sates, it is similar. The largest aquifer in the world, known as the Ogalalla Aquifer, is located beneath the arid lands of the western United States. The **Ogallala aquifer** is very slowly recharged by underground **seepage** that mostly originates with precipitation falling on a distant recharge zone in mountains located in its extreme western range. Much of the groundwater presently in the Ogalalla is **fossil water** that has accumulated during tens of thousands of years of extremely slow **infiltration**. Although the Ogalalla aquifer is an enormous resource, it is being depleted alarmingly by pumping at more than 150,000 wells. Most of the groundwater being withdrawn by the wells is used in irrigated agriculture, and some for drinking and other household purposes. In recent years, the level of the Ogalalla aquifer has been decreasing by as much as 3.2 feet (1 meter) per year in intensively utilized zones, while the recharge rate is only of the order of 1 mm/yr. (or a little over 1/32 of an inch). Obviously, the Ogalalla aquifer is being mined on a large scale.

Aquifer depletion brings with it more than the threat of water **scarcity** for human use. Serious environmental consequences can occur when large amounts of water are pumped rapidly from ground water reservoirs. Commonly, the land above an aquifer will subside or sink as the water is drained from the geologic formation and the earth compacts. In 1999, researchers noted that portions of Bangkok, Thailand and **Mexico City, Mexico** were sinking as a result of overexploitation of their aquifers. This can cause foundations of buildings to shift and may even contribute to **earthquake** incidence. Large cities in the United States like Albuquerquer, Phoenix, and Tuscon lie over aquifers that are being rapidly depleted.

Unfortunately, the current solutions to aquifer depletion are to drill wells deeper or abandon irrigated agriculture and import food. Both are costly choices for any country, both in dollars and in economic independence.

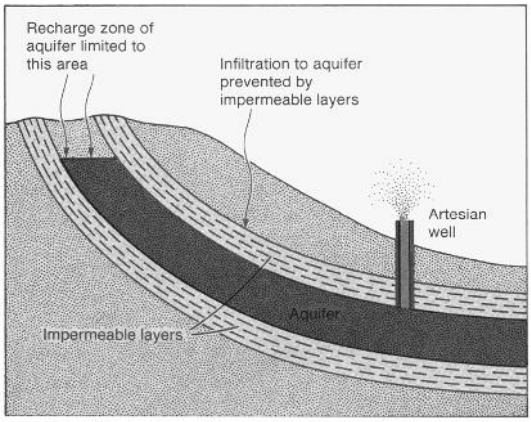
Aquifer restoration

Once an **aquifer** is contaminated, the process of restoring the quality of water is generally time-consuming and expensive, and it is often more cost effective to locate a new source of water. For these reasons, the restoration of an aquifer is usually evaluated on the basis of these criteria: 1) the potential for additional contamination; 2) the time period over which the contamination has occurred; 3) the type of contaminant; and 4) the **hydrogeology** of the site. Restoration techniques fall into two major categories, in-situ methods

and conventional methods of withdrawal, treatment, and disposal.

Remedies undertaken within the aquifer involve the use of chemical or biological agents which either reduce the toxicity of the contaminants or prevent them from moving any further into the aquifer, or both. One such method requires the introduction of biological cultures or chemical reactants and sealants through a series of injection **wells**. This action will reduce the toxicity, form an impervious layer to prevent the spread of the contaminant, and clean the aquifer by rinsing. However, a major drawback to this approach is the difficulty and expense of installing enough injection wells to assure a uniform distribution throughout the aquifer.



In-situ degradation, another restoration method, can theoretically be accomplished through either biological or chemical methods. Biological methods involve placing **microorganisms** in the aquifer that are capable of utilizing and degrading the hazardous contaminant. A great deal of progress has been made in the development of microorganisms which will degrade both simple and complex organic compounds. It may be necessary to supplement the organisms introduced with additional nutrients and substances to help them degrade certain insoluble organic compounds. Before introduction of these organisms, it is also important to evaluate the intermediate products of the degradation to **carbon dioxide** and water for toxicity. Chemical methods of in-situ degradation fall into three general categories: 1) injection of neutralizing agents for **acid** or caustic compounds; 2) addition of oxidizing agents such as **chlorine** or **ozone** to destroy organic compounds; and 3) introduction of amino acids to reduce PCBs (**polychlorinated biphenyls**).

There are also methods for stabilizing an aquifer and preventing a contaminant **plume** from extending. One stabilizing alternative is the conversion of a contaminant to an insoluble form. This method is limited to use on inorganic salts, and even those compounds can dissolve if the physical or chemical properties of the aquifer change. A change in **pH**, for instance, might allow the contaminant to return to solution. Like other methods of in-situ restoration, conversion requires the contaminant to be contained within a workable area.

The other important stabilizing alternatives are containment methods, which enclose the contaminant in an insoluble material and prevent it from spreading through the rest of the aquifer. There are partial and total containment methods. For partial containment, a clay cap can be applied to keep rainfall from moving additional contaminants into the aquifer. This method has been used quite often where there are sanitary landfills or other types of **hazardous waste** sites. Total containment methods are designed to isolate the area of contamination through the construction of some kind of physical barrier, but these have limited usefulness. These barriers include **slurry** walls, grout curtains, sheet steel and floor **seals**. Slurry walls are usually made of concrete, and are put in place by digging a trench, which is then filled with the slurry. The depth at which these walls can be use is limited to 80–90 ft (24–27 m). Grout curtains are formed by injecting a cement grout under pressure into the aquifer through a series of injection wells, but it is difficult to know how effective a barrier this is and whether it has uniformly penetrated the aquifer. Depth is again a limiting factor, and this method has a range of 50–60 ft (15–18 m). Steel sheets can be driven to a depth of 100 ft (30 m) but no satisfactory technique for forming impermeable joints between the individual sheets has been developed. Floor seals are grouts installed horizontally, and they are used where the contaminant plume has not penetrated the entire depth of the aquifer. None of these methods offers a permanent solution to the potential problems of contamination, and some type of continued monitoring and maintenance is necessary.

Conventional methods of restoration involve removal of the contaminant followed by withdrawal of the water, and final treatment and disposal. Site characteristics that are important include the **topography** of the land surface, characteristics of the **soil**, depth to the **water table** and how this depth varies across the site, and depth to impermeable layers. The options for collection and withdrawal can be divided into five groups: 1) collection wells; 2) subsurface gravity collection drains; 3) impervious grout curtains (as described above); 4) cut-off trenches; or 5) a combination of these options. Collection wells are usually installed in a line, and are designed to withdraw the contaminant plume and to keep movement of other clean water into the wells at a minimum. Various sorts of drains can be effective in intercepting the plume, but they do not work in deep aquifers or hard rock. Cut-off trenches can be dug if the contamination is not too deep, and water can then be drained to a place where it can be treated before final **discharge** into a lake or stream.

Water taken from a contaminated aquifer requires treatment before final discharge and disposal. To what degree it can be treated depends on the type of contaminant and the effectiveness of the available options. Reverse osmosis uses pressure at a high temperature to force water through a membrane that allows water molecules, but not contaminants, to pass. This process removes most soluble organic **chemicals**, **heavy metals**, and inorganic salts. Ultrafiltration also uses a pressure-driven method with a membrane. It operates at lower temperatures and is not as effective for contaminants with smaller molecules. An **ion exchange** uses a bed or series of tubes filled with a resin to remove selected compounds from the water and replace them with

An aquifer contained between two impermeable layers of of rock or clay. (McGraw-Hill Inc. Reproduced by permission.)

harmless ions. The system has the advantage of being transportable, depending on the type of resin, it can be used more than once by flushing the resin with either an acid or salt solution. Both organic and inorganic substances can be removed using this method.

Wet-air oxidation is another important treatment method. It introduces oxygen into the liquid at a high temperature, which effectively treats inorganic and organic contaminants. Combined ozonation/ultraviolet radiation is a chemical process in which the water containing toxic chemicals is brought into contact with ozone and **ultraviolet radiation** to break down the organic contaminants into harmless parts. Chemical treatment is a general name for a variety of processes that can be used to treat water. They often result in the precipitation of the contaminant, and will not remove soluble organic and inorganic substances. **Aerobic** biological treatments are processes that employ microorganisms in the presence of **dissolved oxygen** to convert organic matter to harmless products. Another approach uses activated **carbon** in columns—the water is run over the carbon and the contaminants become attached to it. Contaminants begin to cover the surface area of the carbon over time, and these **filters** must be periodically replaced.

These treatment processes are often used in combination. The methods used depend on the ultimate disposal plan for the end products. The three primary disposal options are: 1) discharge to a **sewage treatment** plant; 2) discharge to a surface water body; and 3) land application. Each option has positive and negative aspects. Any discharge to a municipal treatment plant requires pre-treatment to standards that will allow the plant to accept the waste. Land application requires an evaluation of plant **nutrient** supplying capability and any potentially harmful side-effects on the crops grown. Discharge to surface water requires that the waste be treated to the standard allowable for that water. For many organics the final disposal method is burning.

Books

Freeze, R. A., and J. A. Cherry. *Ground Water*. Englewood Cliffs, NJ: Prentice-Hall, 1979.

Pye, V. I., R. Patrick, and J. Quarles.*Ground Water Contamination in the United States*. Philadelphia: University of Pennsylvania Press, 1983.

Arable land

Arable land has **soil** and **topography** suitable for economical and practical cultivation of crops. These range from grains, grasses, and legumes to fruits and vegetables. Permanent pastures and **rangelands** are not considered arable. Forested land is also nonarable, although it can be farmed if the area is cleared and the soil and topography are suitable for cultivation.

Aral Sea

The Aral Sea is a large, shallow, saline lake hidden in the remote deserts of the republics of Uzbekistan and Kazakhstan in the south-central region of the former Soviet Union. Once the world's fourth largest lake in area (smaller only than America's Lake Superior, Siberia's **Lake Baikal**, and East Africa's Lake Victoria), in 1960 the Aral Sea had a surface area of 26,250 mi^2 (68,000 km^2), and a volume of 260 cu mi (1,090 cu km). Its only water sources are two large rivers, the Amu Darya and the Syr Darya. Flowing northward from the Pamir Mountains on the Afghan border, these rivers pick up salts as they cross the Kyzyl Kum and Kara Kum deserts. Evaporation from the landlocked sea's surface (it has no outlet) makes the water even saltier.

The Aral Sea's destruction began in 1918 when plans were made to draw off water to grow cotton, a badly needed **cash crop** for the newly formed Soviet Union. The amount of irrigated cropland in the region was expanded greatly (from 7.2–18.8 million acres; 2.9–7.6 million ha) in the 1950s and 1960s with the completion of the Kara Kum canal. Annual water flows in the Amu Darya and Syr Darya dropped from about 13 cu mi (55 cu km) to less than 1 cu mi (5 cu km). In some years the rivers were completely dry when they reached the lake.

Soviet authorities were warned that the sea would die without replenishment, but sacrificing a remote **desert** lake for the sake of economic development seemed an acceptable

tradeoff. Inefficient **irrigation** practices drained away the lifeblood of the lake. Dry years in the early 1970s and mid-1980s accelerated water shortages in the region. Now, in a disaster of unprecedented magnitude and rapidity, the Aral Sea is disappearing as we watch.

Until 1960 the Aral Sea was fairly stable, but by 1990, it had lost 40% of its surface area and two-thirds of its volume. Surface levels dropped 42 ft; 914 m), turning 11,580 mi^2 (30,000 km^2, about the size of the state of Maryland) of former seabed into a salty, dusty desert. Fishing villages that were once at the sea's edge are now 25 mi (40 km) from water. Boats trapped by falling water levels lie abandoned in the sand. **Salinity** of the remaining water has tripled and almost no aquatic life remains. **Commercial fishing** that brought in 48,000 metric tons in 1957 was completely gone in 1990.

Winds whipping across the dried-up seabed pick up salty dust, **poisoning** crops and causing innumerable health problems for residents. An estimated 43 million metric tons of salt are blown onto nearby fields and cities each year. Eye irritations, intestinal diseases, skin infections, **asthma**, **bronchitis**, and a variety of other health problems have risen sharply in the past 20 years, especially among children. Infant **mortality** in the Kara-Kalpak Autonomous Region adjacent to the Aral Sea is 60 per 1,000, twice as high as in other former Soviet Republics.

Among adults, throat cancers have increased five fold in 30 years. Many physicians believe that heavy doses of pesticides used on the cotton fields and transported by **runoff** water to the lake sediments are now becoming airborne in dust storms. Although officially banned, DDT and other persistent pesticides have been widely used in the area and are now found in mothers' milk. More than 35 million people are threatened by this disaster.

A report by the Institute of Geography of the Russian Academy of Sciences predicts that without immediate action, the Aral Sea will vanish by 2010. It is astonishing that such a large body of water could dry up in such a short time. Philip P. Micklin of Western Michigan University, an authority on water issues says this may the world's largest ecological disaster.

What can be done to avert this calamity? Clearly, one solution would be to stop withdrawing water for irrigation, but that would compound the disastrous economic and political conditions in the former Soviet Republics. More efficient irrigation might save as much as half the water now lost without reducing crop yields, but lack of funds and organization in the newly autonomous nations makes new programs and improvements almost impossible. Restoring the river flows to about 5 cu mi (20 cu km) per year would probably stabilize the sea at present levels. It would take perhaps twice as much to return it to 1960 conditions.

Before the dissolution of the Soviet Union, there was talk of grandiose plans to divert part of the northward-flowing Ob and Irtysh rivers in Western Siberia. In the early 1980s a system of **dams**, pumping stations, and a 1,500 mi (2,500 km) canal was proposed to move 25 cu km (6 cu mi) of water from Siberia to Uzbekistan and Kazakhstan. The cost of 100 billion rubles ($150 billion) and the potential adverse environmental effects led President Mikhail Gorbachev to cancel this scheme in 1986.

Perhaps more than technological fixes, what we all need most is a little foresight and humility in dealing with **nature**. The words painted on the rusting hull of an abandoned fishing boat lying in the desert might express it best, "Forgive us Aral. Please come back."

Arco, Idaho

"Electricity was first generated here from Atomic Energy on December 20, 1951. On December 21, 1951, all of the electrical power in this building was supplied from Atomic Energy."

Those words are written on the wall of a nuclear reactor in Arco, Idaho, a site now designated as a Registered National Historic Landmark by the **U.S. Department of the Interior**. The inscription is signed by 16 scientists and engineers responsible for this event.

The production of electricity from **nuclear power** was truly a momentous occasion. Scientists had known for nearly two decades that such a conversion was possible. Use of nuclear energy as a safe, efficient energy source of power was regarded by many people in the United States and around the world as one of the most exciting prospects for the "world of tomorrow."

Until 1945, scientists' efforts had been devoted to the production of **nuclear weapons**. The conclusion of World War II allowed both scientists and government officials to turn their attention to more productive applications of nuclear energy. In 1949, the United States **Atomic Energy Commission** (AEC) authorized construction of the first nuclear reactor designed for the production of electricity. The reactor was designated Experimental Breeder Reactor No. 1 (EBR-I).

The site chosen for the construction of EBR-I was a small town in southern Idaho named Arco. Founded in the late 1870s, the town had never grown very large. Its population in 1949 was 780. What attracted the AEC to Arco was the 400,000 acres (162,000 ha) of lava-rock-covered wasteland around the town. The area provided the seclusion that seemed appropriate for an experimental nuclear reactor. In addition, AEC scientists considered the possibility that the porous lava around Arco would be an ideal place in which to dump wastes from the reactor.

On December 21, 1951, the Arco reactor went into operation. Energy from a **uranium** core about the size of a football generated enough electricity to light four 200-watt light bulbs. The next day its output was increased to a level where it ran all electrical systems in EBR-I. In July 1953, EBR-I reached another milestone. Measurements showed that breeding was actually taking place within the reactor. The dream of a generation had become a reality.

The success of EBR-I convinced the AEC to expand its breeder experiments. In 1961, a much larger version of the original plant, Experimental Breeder Reactor No. 2 (EBR-II) was also built near Arco on a site now designated as the Idaho National Engineering Laboratory of the **U.S. Department of Energy**. EBR-II produced its first electrical power in August of 1964.

Arctic Council

The Arctic Council is a cooperative environmental protection council composed of eight governments whose goal is to protect the Arctic's fragile **environment** while continuing economic development. Established in 1996, the Council plans to protect the environment by protecting **biodiversity** in the Arctic region and maintaining the sustainable use of its **natural resources**.

The Arctic Council was formed on September 19, 1996, when representatives from Canada, Denmark, Finland, Iceland, Norway, the Russian Federation, Sweden, and the United States signed a *Declaration on the Establishment of the Arctic Council*. The work and programs founded under the former Arctic Environmental Protection Strategy (AEPS) have become integrated into the new Arctic Council, which provides for indigenous representation—including the Inuit Circumpolar Conference, the Saami Council (Scandinavia, Finland, and Russia) for the Nordic areas and the Association of Indigenous Minorities of the North, Siberia, and the Far East of the Russian Federation—at all meetings. The indigenous people cannot vote but may provide knowledge of traditional practices for research and a collective understanding of the Arctic. As members of the Council's board, they can recommended ways to spread the work and benefits of **oil drilling** and mining businesses among indigenous communities while minimizing the negative effects on their land.

The **World Wildlife Fund** oversees the Council's work on protecting the Arctic's **wildlife** and vegetation from various destructive activities, such as diamond mining and **clear-cutting**. There is also evidence that the Arctic area receives a disproportionate amount of **pollution**, as witnessed in the overall land and water degradation.

Former Canadian Environment Minister Sergio Marchi is a supporter of the Council's work, emphasizing "The Arctic is an environmental early warning system for our globe. The Arctic Council will help deliver that warning from pole to pole."

Arctic haze

The dry **aerosol** present in arctic regions during much of the year and responsible for substantial loss of **visibility** through the **atmosphere**. The arctic regions are, for the most part, very low in precipitation, qualifying on that basis as deserts. Ice accumulates because even less water evaporates than is deposited. Hence, particles that enter the arctic atmosphere are only very slowly removed by precipitation, a process that removes a significant fraction of particles from the tropical and temperate atmospheres. Thus, relatively small sources can lead to appreciable final atmospheric concentrations.

A **succession** of studies has been conducted on the chemistry of the particles in that **haze**, and those trapped in the snow and ice. Much of the time the mix of trace elements in the particles is very close to that found in the industrial emissions from northern Europe and Siberia and quite different from that in such emissions from northern North America. Concentrations decrease rapidly with depth in the ice layers, indicating that these trace elements began to enter the atmosphere within the past few centuries. It is now generally conceded that most of the haze particles are derived from human activities, primarily—though not exclusively—in northern Eurasia.

Since the haze scatters light, including sunlight, it decreases the **solar energy** received at the ground level in polar regions and may, therefore, have the potential to decrease arctic temperatures. Arctic haze also constitutes a nuisance because it decreases visibility. The trace elements found in arctic haze apparently are not yet sufficiently concentrated in either atmosphere or precipitation to constitute a significant toxic hazard.

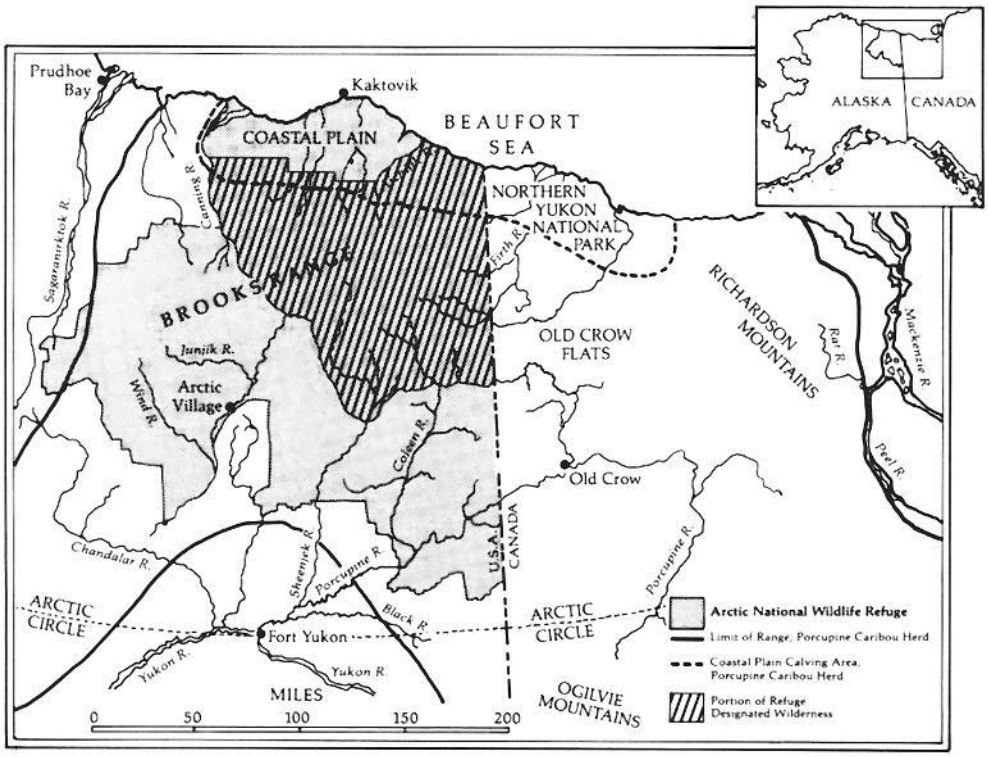
Arctic National Wildlife Refuge

Beyond the jagged Brooks Range in Alaska's far northeastern corner lies one of the world's largest **nature** preserves, the 19.8-million acre (8-million ha) Arctic **National Wildlife Refuge** (ANWR). A narrow strip of treeless coastal plain in the heart of the refuge presents one of nature's grandest spectacles, as well as one of the longest-running environmental battles of the past century. For a few months during the brief arctic summer, the **tundra** teems with **wildlife**. This is the calving ground of the 130,000 caribou of the Porcupine herd, which travels up to 400 mi (640 km) each summer to graze and give birth along the Arctic Ocean shore. It also is important **habitat** for tens of thousands of snow geese, tundra swans, shorebirds and other migratory waterfowl; a denning area for polar bears, arctic foxes and arctic **wolves**; and a year-round home to about 350 shaggy musk ox. In wildlife density and diversity, it rivals Africa's Serengeti.



When Congress established the **Wildlife Refuge** in 1980, a special exemption was made for about 600,000 ha (1.5 million acres) of coastline between the mountains and the Beaufort Sea where geologists think sedimentary strata may contain billions of barrels of oil and trillions of cubic feet of **natural gas**. Called the 1002 area for the legislative provision that put it inside the wildlife refuge but reserved the right to drill for **fossil fuels**, this narrow strip of tundra may be the last big, on-shore, liquid **petroleum** field in North America. It also is **critical habitat** for one of the richest biological communities in the world. The possibility of extracting the fossil fuels without driving away the wildlife and polluting the pristine landscape is supported by oil industry experts and disputed by biologists and environmentalists.

The amount of oil and gas beneath the tundra is uncertain. Only one seismic survey has been done and a few test **wells** drilled. Industry geologists claim that there may be 16 billion barrels of oil under ANWR, but guessing the size and content of the formation from this limited evidence is as much an art as a science. Furthermore, the amount of oil it's economical to recover depends on market prices and shipping costs. At current wholesale prices of $25 per barrel, the U.S. **Geological Survey** estimates that 7 billion barrels might be pumped profitably. If prices drop below $10 per barrel, as they did in the early 1990s, the economic resource might be only a few hundred million barrels.

Energy companies are extremely interested in ANWR because any oil found there could be pumped out through the existing **Trans-Alaska pipeline**, thus extending the life of their multibillion-dollar investment. The state of Alaska hopes that revenues from ANWR will replenish dwindling coffers as the oil supply from near-by Prudhoe Bay wells dry up. **Automobile** companies, tire manufacturers, filling stations, and others who depend on our continued use of petroleum argue that domestic oil supplies are rapidly being depleted, leaving the United States dependent on foreign countries for more than half of its energy consumption.

Oil drilling proponents point out that prospecting will occur only in winter when the ground is covered with snow and most wildlife is absent or hibernating. Once oil is located, they claim, it will take only four or five small drilling areas, each occupying no more than a few hundred hectares, to extract it. Heavy equipment would be hauled to the sites during the winter on ice roads built with water pumped from nearby lakes and rivers. Each two-meter-thick, gravel drilling pad would hold up to 50 closely spaced wells, which would penetrate the **permafrost** and then spread out horizontally to reach pockets of oil up to 6 mi (10 km) away from the wellhead. A central processing facility would strip water and gas from the oil, which would then be pumped through elevated, insulated pipelines to join oil flowing from Prudhoe Bay.

Opponents of this project argue that the noise, **pollution**, and construction activity accompanying this massive operation will drive away wildlife and leave scars on the landscape that could last for centuries. Pumping the millions

A map of the Arctic National Wildlife Refuge (ANWR) in Alaska. (Map by World Management. Reproduced by permission.)

of gallons of water needed to build ice roads could dry up local ponds on which wildlife depends for summer habitat. Every day six to eight aircraft—some as big as the C-130 Hercules—would fly into ANWR. The smell of up to 700 workers and the noise of numerous trucks and enormous power-generating turbines, each as large and loud as a jumbo aircraft engine, would waft out over the tundra. Pointing to the problems of other Arctic oil drilling operations where drilling crews dumped **garbage**, sewage, and toxic drilling waste into surface pits, environmentalists predict disaster if drilling is allowed in the refuge. Pipeline and drilling spills at Prudhoe Bay have contaminated the tundra and seeped into waterways. And scars from bulldozer tracks made 50 years ago can still be seen clearly today. John Adams, President of the **Natural Resources Defense Council** claims that the once pristine wildlife habitat of Prudhoe Bay has become a toxic, industrial wasteland.

Oil companies planning to drill in ANWR, on the other hand, claim that old, careless ways are no longer permitted in their operations. Wastes are collected and either burned or injected into deep wells. Although some animals do seem to have been displaced at Prudhoe Bay, the Central Arctic herd with 27,000 caribou is five times larger now than it was in 1978 when drilling operations began there. But in ANWR the Porcupine herd has five times as many animals crowded into one-fifth the area and may be much more sensitive to disturbance than their cousins to the west.

Native people are divided on this topic. The coastal Inupiat people, many of whom work in the oil fields, support opening the refuge to oil exploration. They hope to use their share of the oil revenues to build new schools and better housing. The Gwich'in people, who live south of the refuge, would gain nothing from oil exploitation. They worry that migrating caribou on which they depend might be decline as a result of drilling on critical calving grounds.

Even if ANWR contains seven billion barrels of oil, it will take at least a decade to begin to get it to market and the peak production rate will probably be about one million barrels of oil per day in 2030. Flow from the 1002 area would then meet less than 4% of the U.S. daily oil consumption. Improving the average fuel efficiency of all cars and light trucks in America by just one mile per gallon would save more oil than is ever likely to be recovered from ANWR,

and it would do so far faster and cheaper than extracting and transporting crude oil from the arctic. Cutting our fossil fuel consumption also is vital if we are to avoid catastrophic global **climate** change.

In 1995, Congress passed a budget that included a provision to allow drilling in ANWR, but President Bill Clinton vetoed the bill. In 2002, the Republican-controlled House of Representatives once again passed an energy bill that authorized oil and gas exploration in ANWR. President Bush strongly supported this bill and promised to sign it if given an opportunity. The Senate energy bill, however, rejected ANWR drilling by a vote of 54 to 46, and the measure was abandoned by its sponsors.

Undoubtedly, this debate won't disappear anytime soon. With a potential of billions of dollars to be made from oil and gas formations, the industry won't give up easily. For many conservatives, this issue has become a matter of principle. They believe we have both a right and a duty to exploit the resources available to us. Environmental groups feel equally strongly about the value of wildlife, **wilderness**, and one of the "last remaining great places" in the world. Protecting this harsh but beautiful land garnered more donations and public passions than any other environmental issue in the past decade. Clearly, how we decide to manage ANWR will be a landmark in **environmental history**.

Arid

Arid lands are dry areas or deserts where a shortage of rainfall prevents permanent rain-fed agriculture. They are bordered by, and interact with, marginal or semi-arid lands where the annual rainfall (still only 10–15 in; 25–38 cm) allows limited agriculture and light grazing. However, in many parts of the world human mismanagement, driven by increasing populations, has degraded these areas into unusable arid lands. For example, clearing natural vegetation and **overgrazing** have led to **soil erosion**, reduced land productivity, and ultimately reduced water availability in the region. This degradation of semi-arid lands to deserts, which can also occur naturally, is known as **desertification**.

Arid landscaping

Arid landscaping, or xeriscaping (from the Greek word *xeros*, meaning dry), is the integration of practicality and beauty in drought-prone public and private gardens. Xeriscaping is part of a larger trend among environmentalist gardeners to incorporate native rather than imported **species** within local ecosystems.

In drought-prone areas like California, where **water conservation** is imperative and lawns and flower gardens are at risk, gardeners have taken several steps to cope with **drought**. A 20-by-40-ft (6-by-12 m) green lawn requires about 2,500 gal (9,475 l) of water a month, enough for a four-member family for 10 days. Some arid landscapers eliminate lawns altogether and replace them with flagstone or concrete walkways; others aerate the **soil** or cut the grass higher for greater water retention. More popular is replacing imported grasses with native grasses, already adapted to the local **climate**, and letting them grow without being cut.

Some big trees, such as oak, do better in drought than others, such as birches or magnolias. To save big trees that are expensive and important providers of shade, some gardeners place "soaker" hoses, in which water flows out through holes in the length of the hose in concentric circles at the base of trees and water them deeply once or twice a season.

More commonly, arid landscapers replace water-loving shrubs and trees with those best adapted to drought conditions. These include some herbs, such as rosemary, thyme, and lavender, and shrubs like the silvery santolina, which are important in color composition of gardens.

Other plants that grow well in semi-arid and arid conditions are legumes (Leguminosae), poppies (Papaveraceae), daisies (Compositae), black-eyed susans (*Rudbeckia fulgida*), goldenrod (*Solidago*), honeysuckle (*Lonicera*), sunflowers (*Helianthus*), daylilies (*Hemerocallis*), and eucalyptus. Generally, drought-resistant plants have silvery leaves that reflect sunlight (*argentea*); hairy (*tomentosum*) or stiff haired (*hirsuta*) leaves that help retain moisture; long narrow leaves (*angustifolia*), threadlike leaves (*filimentosa*), and aromatic leaves (*aromatica*) that provide a moisture-protecting **haze** in heat.

Drip irrigation, hoses with small regular holes, whose amount is regulated by timers, is the most efficient xeriscape watering technique. Mulching with dead leaves, pine bark, straw, and other organic matter helps retain soil moisture. Soil types are a critical part of arid landscaping: one inch (2.5 cm) of water, for example, will penetrate 6–8 in (15–

20 cm) into loam (a sand, peat, and clay mixture), but only 4–5 in (10–13 cm) into dense clay.

Arid landscapers monitor plant health and soil dryness only when necessary, often in the early morning or in the evening to avoid evaporation by the sun. **Recycling** "gray" water, **runoff** from household sinks and washing machines, is best if the water is used quickly before bacteria collects and if laundry **detergents** are **biodegradable**. Arid landscapers, using native and drought-resistant plant species in conjunction with stone and concrete walkways and **mulch**, create gardens that are not only aesthetically pleasing but ecologically healthy.

Army Corps of Engineers

The United States Army Corps of Engineers, headquartered in Washington, D.C., is the world's largest engineering organization. The Corps was founded on June 16, 1775, the eve of the Battle of Bunker Hill, as the Continental Army fought cannon bombardments from British ships.

From early in the history of the Corps, the organization has handled both military and civil engineering needs of the United States. In earlier times those needs included coastal fortifications and lighthouses, surveying and exploring the frontier, construction of public buildings, snagging and clearing river channels, and operating early national parks such as Yellowstone. Under Corps' direction, the Panama Canal and **St. Lawrence Seaway** were built, and the Corps administered the Manhattan Project which led to the development of the atomic bomb during World War II.

Today, the Corps of Engineers provides engineering and related services in four areas: water and natural resource management (civil works), military construction and support, engineering research and development, and support to other government agencies.

In its military role, the Corps of Engineers provides support on the battlefield, enhancing movement and operations of American forces while impeding or delaying enemy actions. Corps engineers also plan, design, and supervise construction of military facilities and operate and maintain Army installations worldwide.

In its civil role, the Corps is responsible for the development of the nation's **water resources** and the operation and maintenance of completed water resource projects. Emerging engineering needs include renewal of infrastructure, management and control of **wetlands** development and **ocean dumping**, **waste management**, including hazardous and toxic waste, **solid waste**, and nuclear waste, and disaster response and preparedness.

The Corps undertook the task of "unstraightening" the Kissimmee River in south Florida. The river had been straightened into a canal for flood control between 1961 and 1971, losing half its length and most of its marshes. In the first reversal of a Corps' project, the river is slated to regain its curves. The restoration is due to be completed in 2005, but already there have been an increase in the **flora** and **fauna** around the developed areas.

The Corps employees more than 48,000 military and civilian members, has 13 regional headquarters, 39 district offices, and four major laboratories and research centers throughout the country.

Svante August Arrhenius (1859 – 1927)

Swedish chemist and physicist

Young Svante gave evidence of his intellectual brilliance at an early age. He taught himself to read by the age of three and learned to do arithmetic by watching his father keep books for the estate of which he was in charge. Arrhenius began school at the age of eight, when he entered the fifth-grade class at the Cathedral School in Uppsala. After graduating in 1876, Arrhenius enrolled at the University of Uppsala.

At Uppsala, Arrhenius concentrated on mathematics, chemistry, and physics and passed the candidate's examination for the bachelor's degree in 1878. He then began a graduate program in physics at Uppsala, but left after three years of study. He was said to be dissatisfied with his physics advisor, Tobias Thalén, and felt no more enthusiasm for the only advisor available in chemistry, Per Theodor Cleve. As a result, he obtained permission to do his doctoral research in absentia with the physicist Eric Edlund at the Physical Institute of the Swedish Academy of Sciences in Stockholm.

The topic Arrhenius selected for his dissertation was the electrical conductivity of solutions. In 1884 Arrhenius submitted his thesis on this topic. In the thesis he hypothesized that when salts are added to water, they break apart into charged particles now known as ions. What was then thought of as a molecule of sodium chloride, for example, would dissociate into a charged sodium atom (a sodium **ion**) and a charged **chlorine** atom (a chloride ion). The doctoral committee that heard Arrhenius's presentation in Uppsala was totally unimpressed by his ideas. Among the objections raised was the question of how electrically charged particles could exist in water. In the end, the committee granted Arrhenius his Ph.D., but with a score so low that he did not qualify for a university teaching position.

Convinced that he was correct, Arrhenius had his thesis printed and sent it to a number of physical chemists on the continent, including Rudolf Clausius, Jacobus van't Hoff, and Wilhelm Ostwald. These men formed the nucleus of a group of researchers working on problems that overlapped chemistry and physics, developing a new discipline that would ultimately be known as physical chemistry. From this group, Arrhenius received a much more encouraging response than he had received from his doctoral committee. In fact, Ostwald came to Uppsala in August 1884 to meet Arrhenius and to offer him a job at Ostwald's Polytechnikum in Riga. Arrhenius was flattered by the offer and made plans to leave for Riga, but eventually declined for two reasons. First, his father was gravely ill (he died in 1885), and second, the University of Uppsala decided at the last moment to offer him a lectureship in physical chemistry.

Arrhenius remained at Uppsala only briefly, however, as he was offered a travel grant from the Swedish Academy of Sciences in 1886. The grant allowed him to spend the next two years visiting major scientific laboratories in Europe, working with Ostwald in Riga, Friedrich Kohlrausch in Würzburg, Ludwig Boltzmann in Graz, and van't Hoff in Amsterdam. After his return to Sweden, Arrhenius rejected an offer from the University of Giessen, Germany, in 1891 in order to take a teaching job at the Technical University in Stockholm. Four years later he was promoted to professor of physics there. In 1903, during his tenure at the Technical University, Arrhenius was awarded the Nobel Prize in chemistry for his work on the dissociation of electrolytes.

Arrhenius remained at the Technical University until 1905 when, declining an offer from the University of Berlin, he became director of the physical chemistry division of the Nobel Institute of the Swedish Academy of Sciences in Stockholm. He continued his association with the Nobel Institute until his death in Stockholm on October 2, 1927.

Although he was always be remembered best for his work on dissociation, Arrhenius was a man of diverse interests. In the first decade of the twentieth century, for example, he became especially interested in the application of physical and chemical laws to biological phenomena. In 1908 Arrhenius published a book entitled *Worlds in the Making* in which he theorized about the transmission of life forms from planet to planet in the universe by means of spores.

Arrhenius's name has also surfaced in recent years because of the work he did in the late 1890s on the **greenhouse effect**. He theorized that **carbon dioxide** in the **atmosphere** has the ability to trap heat radiated from the earth's surface, causing a warming of the atmosphere. Changes over time in the concentration of **carbon** dioxide in the atmosphere would then, he suggested, explain major climatic variations such as the glacial periods. In its broadest outlines, the Arrhenius theory sounds similar to current speculations about **climate** changes resulting from global warming.

Among the honors accorded Arrhenius in addition to the Nobel Prize were the Davy Medal of the Royal Society (1902), the first Willard Gibbs Medal of the Chicago section of the American Chemical Society (1911), and the Faraday Medal of the British Chemical Society (1914).

Arsenic

Arsenic is an element having an atomic number of 33 and an atomic weight of 74.9216 that is listed by the U.S. **Environmental Protection Agency** (EPA) as a hazardous substance (**Hazardous waste** numbers P010, P012) and as a **carcinogen**. *The Merck Index* states that the symptoms of acute **poisoning** following arsenic ingestion are irritation of the gastrointestinal tract, nausea, vomiting, and diarrhea that can progress to shock and death. According to the 2001 Update Board on Environmental Studies and Toxicology, such toxic presentations generally require weeks to months of exposure to arsenic at high doses, as much as 0.04mg/kg/day (0.02mg/lb/day). Furthermore, long-term, or chronic poisoning can result in skin thickening, exfoliation, and hyperpigmentation. Continuing exposure also has been associated with development of herpes, peripheral neurological manifestations, and degeneration of the liver and kidneys. Of primary importance, however, is the association of chronic arsenic exposure with increased risk of developing high blood

pressure, cardiovascular disease, and skin **cancer**, diseases that are increasing public health concerns.

Variations of arsenic were used in everyday life. In the early nineteenth century, it was discovered that a fungus, *Scopulariopsis brevicaulis*, was eating away at the starches found in certain forms of wallpaper. The fungus also altered the arsenate dyes, changing them into trimethylarsine oxide, which is further converted to the extremely toxic trimethylarsine gas. The gas was then released into the room, killing the people who spent long amounts of time there, usually sleeping. This process was discovered in 1897 but the gas itself was not discovered and named until 1945.

Safe drinking water standards are regulated by the EPA in the United States. In February 2002, the EPA revised the former standard for acceptable levels of arsenic in drinking water. The revision of the **Safe Drinking Water Act** reduced the standard from 50 **parts per billion** (ppb) to 10 ppb of arsenic as the acceptable level for drinking water. The regulation requires that all states must comply with the new standard by January 2006. Sources of arsenic contamination of drinking water include **erosion** of natural deposits and run-off of waste from glassmaking and electronics industries. Also, arsenic is used in insecticides and rodenticides, although much less widely than it once was due to new information regarding its toxicity.

Arsenic-treated lumber

Arsenic-treated wood is wood that has been pressure-treated with a **pesticide** containing inorganic **arsenic** (i.e., the arsenic compound does not contain **carbon**) to protect it from dry rot, **fungi**, molds, termites, and other pests. The arsenic can be a part of a CCA (chromated **copper** arsenate) chemical mixture consisting of three pesticidal compounds, copper, chromate, and arsenic; the most commonly used type of CCA contains 34% arsenic as arsenic pentoxide. Less commonly used wood preservatives containing arsenic include the pesticide ACA (ammoniacal copper arsenate), which contains ammonium, copper, and arsenic, and the pesticide ACZA (ammoniacal copper zinc arsenate), which contains ammonia, copper, zinc, and arsenic. In 1996, the United States wood product industry used 30 million pounds of arsenic, or half of all the arsenic produced worldwide.

Inorganic arsenic in CCA has been used since the 1940s. CAA is injected into wood through a process that uses high pressure to saturate wood products with the **chemicals**. Preserved wood products, such as utility poles, highway noise barriers, sign posts, retaining walls, boat bulkheads, dock pilings, and wood decking, are used in the construction, railroad, and utilities industries. Historically CCA has been the principal chemical used to treat wood for outdoor uses around a home. Residential uses of arsenic-treated woods include play structures, decks, picnic tables, gazebos, landscaping timbers, residential fencing, patios, and walkways/boardwalks. After wood is pressure-treated with arsenic compounds, residues of the preservatives can remain on the surface. The initial residues wash off, but as the wood weathers, new layers of treated wood and pesticides are exposed. Arsenic is also present in paints that are used to cover the cut ends of treated wood. Freshly arsenic-treated wood, if not coated, has a greenish tint, which fades over time.

Arsenic is acutely toxic. Contact with arsenic may cause irritation of the stomach, intestines, eyes, nose, and skin, blood vessel damage, and reduced nerve function. In addition, according to the **National Academy of Sciences** and the **National Research Council**, exposure to arsenic increases the risk of human lung, bladder, and skin **cancer** over a lifetime and is suspected as a cause of kidney, prostate, and nasal passage cancer. The National Academy of Sciences and the Science Advisory Board of the United States **Environmental Protection Agency** has also reported that arsenic may cause high blood pressure, cardiovascular disease, and diabetes.

Arsenic may enter the body through the skin, by ingestion, or by inhalation. Ingestion occurs most frequently when contaminated hands are put in the mouth, or when contaminated hands are used for eating food. Repeated exposure will increase risks of adverse health effects. Splinters of wood piercing the skin may also be a means of entry of arsenic into the body, but the importance of this route has not been well-studied.

The use of most pesticides containing arsenic had been banned by the United States Environmental Protection Agency, but in 1985 CCA was designated as a restricted-use pesticide. However, CCA-treated wood products were not regulated like the pesticides the wood products contained because it was assumed that the pesticides would stay in the wood. Unfortunately adequate information was not available on whether arsenic is fixed in the wood permanently and whether the wood product is safe. It is known that fixation of the chemicals in the wood matrix is enhanced if the treated wood is wrapped in tarps and stored for a sufficient length of time, which varies with the temperature. For example, to achieve fixation, the wood must be stored for 36 days in 50° F (21° C) weather and for 12 days in 70° F (10° C) weather. At 32° F., no fixation occurs.

However, research by the Florida Center for Solid and Hazardous **Waste Management** and the Connecticut Agricultural Experiment Station suggests that **leaching** of arsenic into the soils or into surface water under CCA-treated structures occurs at greater than safe levels. Florida studies showed that arsenic was found in soils underneath the eight pressure treated decks that were investigated. Of

73 samples taken, 61 samples had levels of arsenic higher than the Florida clean up levels for industrial sites. One sample had arsenic levels 300 times higher than the state's mandated clean up level.

Based on the potential for adverse health effects, the United States Protection Agency announced in February 2002 that the use of consumer products made with CCA, including play structures, decks, picnic tables, landscaping timbers, patios, walkways, and board walks, will be phased out voluntarily by the wood treating industry by December 31, 2003. Wood treated prior to December 31, 2003, can still be used, and already-built structures using CCA-treated wood and the **soil** surrounding the structures will not have to be replaced or removed. As of August 2001, Switzerland, Vietnam, and Indonesia had already banned the use of CCA-treated wood, while Germany, Sweden, Denmark, Japan, **Australia**, and New Zealand restricted its use.

The United States Environmental Protection Agency has issued cautionary recommendations to reduce consumer exposure to arsenic-contaminated wood. Treated wood should not be used where the preservative can become a component of water, food or animal feed. Treated wood should not be used where it may come into direct or indirect contact with drinking water, except for uses where there is incidental contact, such as docks and bridges. Treated wood should not be used for cutting boards or counter tops, and food should not be placed directly on treated wood. Children and others should wash their hands after playing or working outdoors, as arsenic may be swallowed from hand-to-mouth activity. Children and pets should be kept out from under-deck areas. Edible plants should not be grown near treated decks or other structures contructed of treated wood. A plastic liner should be placed on the inside of arsenic-treated boards used to frame garden beds. Sawdust from treated wood should not be used as animal bedding, and treated boards should not be used to construct structures for storage of animal feed or human food. Treated wood should not be used in the construction of the parts of beehives that may come into contact with honey.

Only wood that is visibly clean and free of surface residues (e.g., wood that does not show signs of crystallization or resin on its surface) should be used for patios, decks, and walkways. Consumers working with arsenic-treated wood should reduce their exposure by only sawing, sanding, and machining treated wood outdoors and by wearing a dust mask, goggles, and gloves when performing these types of activities. They should also wash all exposed areas of their bodies thoroughly with soap and water before eating, toileting, drinking, or using **tobacco** products. Work clothes should be washed separately from other household clothing before being worn again. Sawdust, scraps, and other construction debris from arsenic-treated wood should not be composted or used as **mulch**, but caught on tarps for disposal off-site. Pressure-treated wood has an exemption from **hazardous waste** regulations and can be disposed of in municipal landfills without a permit. Pressure-treated wood should not be burned in open fires or in stoves, fireplaces, or residential boilers, as both the **smoke** and the ash may contain toxic chemicals. Treated wood from commercial or industrial uses, such as from construction sites, may only be burned in commercial or industrial incinerators or boilers in accordance with state and federal regulations.

The United States Consumer Product Safety Commission has recommended that playground equipment be painted or sealed with a double coat of a penetrating, non-toxic and non-slippery sealant (e.g., oil-based or semi-transparent stains) every one or two years, depending upon wear and **weathering**. However, available data are limited on whether sealants will reduce the **migration** of wood preservative chemicals from CCA-treated wood. Other potential treatments include the use of polyurethane or other hard lacquer, spar varnish, or pain. However, the use of film-forming or non-penetrating stains are not recommended, as subsequent flaking and peeling may later increase exposure to preservatives in the wood. Structures constructed of arsenic-treated wood should be inspected regularly for wood decay and/or structural weakness. If the treated wood cracks and exposes the interior of the wood is still structurally sound, the affected area should be covered with a double coat of a sealant.

Alternatives to the use of arsenic-treated lumber include the use of painted metal, stones or brick, recycled plastic lumber, which may be all plastic or a composite of plastic and wood fiber, lumber that has been treated with an alternative pesticide ACQ (alkaline copper quaternary), which does not contain arsenic, or untreated rot-resistant wood such as cedar and redwood.

Arsenic compounds are referred to as arsenicals.

Artesian well

A well that discharges water held in a confined **aquifer**. Artesian **wells** are usually thought of as wells whose water is free flowing at the land surface. However, there are many other natural systems that can result in such wells. The classic concept of artesian flow involves a basin with a water-intake area above the level of **groundwater discharge**. These systems can include stabilized sand **dunes**; fractured zones along bedrock faults; horizontally layered rock formations; and the intermixing of **permeable** and impermeable materials along glacial margins.

Asbestos

Asbestos is a fibrous mineral silicate, occurring in numerous forms, of which amosite [$Fe_5Mg_2(Si_8O_{22})(OH)_2$] has been shown to cause mesothelioma, squamous cell carcinoma and adenocarcinoma of the lung after long exposure times. This substance has been listed by the **Environmental Protection Agency** (EPA). Lung **cancer** is most likely to occur in those individuals who are exposed to high air-borne doses of asbestos and who also **smoke**. The pathogenic potential of asbestos appears to be related to its aspect ratio (length-to-diameter ratio), size (particles less than 2 micrometers in length are the most hazardous), and to its surface reactivity.

Asbestos exposure causes thickening of and calcified plaques on the lining of the chest cavity. When inhaled it forms "asbestos bodies" in the lungs, yellowish-brown particles created by reactions between the fibers and lung tissue. This disease was first described by W. E. Cooke in 1921 and given the name **asbestosis**. The **latency** period is generally longer than 20 years—the heavier the exposure, the more likely and the earlier is the onset of the disease. In 1935 an association between asbestos and cancer was noted by Kenneth M. Lynch. However, it was not until 1960 that Christopher Wagner demonstrated a particularly lethal association between cancer of the lining of the lungs and asbestos. By 1973 the **National Institute of Occupational Safety and Health** recommended adoption of an occupational standard of two asbestos fibers per cubic centimeter of air.

During this time, many cases of lung cancer began to surface, especially among asbestos workers who had been employed in shipbuilding during World War II. The company most impacted by lawsuits was the Manville Corporation which had been the supplier to the United States government. Manville Corporation eventually sought Title 11 Federal Bankruptcy protection as a result of these law suits.

More recently, the Reserve Mining Company, a taconite (iron ore) mining operation in **Silver Bay**, Minnesota, was involved in litigation over the dumping of **tailings** (wastes) from their operations into Lake Superior. These tailings contained amositic asbestos particles which appeared to migrate into the Duluth, Minnesota water supply. In an extended law suit, Reserve Mining Company was ordered to shut down their operations. One controversial question raised during the legal action was whether cancer could be caused by from drinking water containing asbestos fibers. In other cancer cases related to asbestos, the asbestos was inhaled rather than ingested. Federal courts held that there is reasonable cause to believe that asbestos in food and drink is dangerous—even in small quantities—and ordered Reserve Mining to stop dumping tailings in the lake.

A significant industry has developed for removing asbestos materials from private and public buildings as a result of the tight standards placed on asbestos concentrations by the **Occupational Safety and Health Administration**. At one time, many steel construction materials, especially horizontal beams, were sprayed with asbestos to enhance their **resistance** to fires. Wherever these materials are now exposed to **ambient air** in buildings, they have the potential to create a hazardous condition. The asbestos must either be covered or removed, and another insulating material substituted as great cost. Removal, however, causes its own problems, releasing high concentrations of fibers into the air. Many experts regard covering asbestos in place with a plastic covering to be the best option in most cases. What was once considered a life-saving material for its flame retardancy, now has become a hazardous substance which must be removed and sequestered in sites specially certified for holding asbestos building materials.

Asbestos removal

Asbestos is a naturally occurring mineral, used by humans since ancient times but not extensively until the 1940s. After World War II and for the next 30 years, it was widely used as a construction material in schools and other public buildings. The United States **Environmental Protection Agency** (EPA) estimates that there are asbestos-containing materials in most of the primary and secondary schools as well as in most public and commercial buildings in the nation. It is estimated that 27 million Americans had significant occupational exposure to asbestos between 1940 and 1980. Asbestos has been popular because it is readily avail-

able, low in cost, and has very useful properties. It does not burn, conducts heat and electricity poorly, strengthens concrete products into which it is incorporated, and is resistant to chemical corrosion. It has been used in building materials as a thermal and electrical insulator and has been sprayed on steel beams in buildings for protection from heat in fires. Asbestos has also been used as an acoustical plaster. In 1984, an EPA survey found that approximately 66% of those buildings containing asbestos had damaged asbestos-containing materials in them. The EPA distinguishes between two types of asbestos damage. If the material, when dry, can be crumbled by hand pressure, it is called "friable." If not, it is called "non-friable." The friable form is much more likely to release dangerous fibers into the air. Fluffy, spray-applied asbestos fireproofing material is an example of friable asbestos. Vinyl-asbestos floor tile is an example of a non-friable material, although it too can release fibers when sanded, sawed, or aggressively disturbed.

Growing recognition that asbestos dust is a dangerous air pollutant has led to government regulation of its use and provisions for removal of asbestos and asbestos-containing products from dwellings, schools, and the workplace. In the United States, the Federal Government has taken steps to prevent unnecessary exposure to asbestos since the 1970s. Six different agencies have authority to regulate some aspect of asbestos use in the United States. The authorized agencies are the EPA, **Occupational Safety and Health Administration** (OSHA), **Food and Drug Administration**, Consumer Product Safety Commission, Department of **Transportation**, and the Mine Safety and Health Administration.

The EPA has authority to oversee use of asbestos in commerce and has developed standards controlling its handling and use. It administers the Asbestos Hazard Emergency Response Act (AHERA) of 1986 that regulates asbestos in schools. The Act prescribes management practices and abatement standards for both public and private schools, and it follows a 1979 rule that launched a technical assistance program to aid schools in efforts to identify asbestos-containing materials. AHERA requires schools to develop a management plan concerning their asbestos-containing materials. Schools must appoint an asbestos manager to be responsible for a number of activities, which include implementing a plan to manage asbestos-containing building materials and ensuring compliance with federal asbestos regulations. AHERA also requires local officials to carry out inspections to identify asbestos-containing materials in public and private elementary and secondary schools, and to comply with AHERA's record keeping requirements. The emphasis on asbestos abatement in schools arises from the recognition that children are especially vulnerable to a virulent form of lung **cancer** called mesothelioma caused by asbestos.

The EPA also administers the Asbestos School Hazard Abatement Reauthorization Act (ASHARA) of 1990 which requires that accredited personnel be used to work with asbestos in schools and in public and commercial buildings. The Act sets training requirements for asbestos professionals, contractors, and abatement workers. It is estimated that 733,000 public buildings in the United States (about 20% of the total) have some type of defective or deteriorating asbestos-containing material in them. Asbestos is frequently found in pipe and boiler insulation, caulking putties, joint compounds, linoleum, acoustical plaster, ceiling tiles, and other building components. ASHARA does not require owners of public and commercial buildings to conduct inspections for asbestos-containing materials, but it does require owners who opt for inspections to use accredited inspectors. To obtain accreditation, asbestos workers must take a 4-day, 32-hour EPA-approved training course covering topics such as potential health effects of asbestos exposure, the use of personal protective equipment, and up-to-date work practices. Detached single-family homes and residential apartment buildings of fewer than 10 units are not covered by the Act.

The EPA is also responsible for the 1989 Asbestos Ban and Phase out Rule that was partially overturned by a Federal Court in 1991. Originally, the ban applied to a wide variety of asbestos-containing products including roof coatings, floor tile, brake pads and linings, and pipeline wrap. Although these products and many others were removed from the ban, it still applies to all new uses of asbestos. The ban remains in effect for the sprayed-on asbestos fireproofing that has been prohibited since 1978.

Individual home owners may seek advice from local health officials concerning potential asbestos problems in or on their dwelling. State agencies often publish pamphlets or brochures that offer help in identifying and correcting problems. Common places to find asbestos in homes include wall, ceiling, and pipe insulation in structures built between 1930 and 1950, and in sheet vinyl, vinyl tile, and vinyl adhesive used in floor coverings. These materials are considered safe, and need not be removed unless they are damaged or disturbed. Wall and ceiling surfaces may contain troweled-on or sprayed-on surface material containing asbestos. If the material is hard, firmly attached, and does not produce a powder or dust when hand pressure is applied, it is probably not hazardous. On the exterior of many older homes, a cement asbestos board called Transite™ has been used as sheet or lap siding and has sometimes been shaped to mimic wood shingles. This material, too, is considered safe unless it has been damaged or disturbed. Other asbestos-containing objects in the home include older electrical lamp

Asbestos removal from a building. (Photograph by Eugene Smith. Black Star Publishing Company Inc. Reproduced by permission.)

socket collars, switch and receptacle boxes, fuse boxes, and old-fashioned "knob and tube" wiring. Asbestos is found in insulation blankets of older ovens, dishwashers, water heaters, and freezers. These items need not be removed if they are intact and not damaged.

There is no safe and reliable way for an untrained individual to identify asbestos except to have it analyzed by a competent testing laboratory. In taking a sample for laboratory analysis, it is important that one not release fibers into the air or get them into one's clothes. To avoid this, it is often helpful to spray the material with a fine mist of water before sampling. The material should not be disturbed more than necessary, and the sample for testing should be enclosed in a sealed plastic or glass vial. If asbestos-containing materials must be removed, they should not be placed with other household trash. Local health officials should be contacted for instructions on safe disposal.

Most public buildings with asbestos-containing materials do not pose an immediate risk to the occupants. As long as the asbestos is sealed and not releasing fibers, there is no health threat. Since asbestos is easily disturbed during building alterations, routine maintenance, and even normal use, it is wise to take precautions to control or eliminate exposure. When asbestos-containing objects are identified, removal, encapsulation, and containment may be used to protect occupants. If the objects are damaged or in poor condition, they should be removed. Proper removal techniques must be strictly followed to avoid spreading contamination. Encapsulation is accomplished by sealing objects with an approved chemical sealant. Containment can be accomplished by constructing suitable physical barriers around the objects to contain any fibers that may be released. Air monitoring and inspection of buildings with asbestos-containing material should be performed regularly to be sure that fiber releases have not occurred. Maintenance and operations crews should be notified of an asbestos threat in their building, and they should be taught proper precautions to avoid accidental disturbance.

The Occupational Safety and Health Administration (OSHA), under the jurisdiction of the United States Department of Labor, is charged with protection of worker safety on the job. OSHA estimates that 1.3 million employees in construction and general industry face signifi-

cant asbestos exposure in the workplace. Greatest exposure occurs in the construction industry, especially while removing asbestos during renovation or demolition. Workers are also apt to be exposed during the manufacture of asbestos products and during **automobile** brake and clutch repair work. OSHA has set standards for maximum exposure limits, protective clothing, exposure monitoring, hygiene facilities and practices, warning signs, labeling, record keeping, medical exams, and other aspects of the workplace. Workplace exposure for workers in general industry and construction must be limited to 0.2 asbestos fibers per 0.061 cu in. of air (0.2 f/cc), averaged over an eight-hour shift, or 1 fiber per 0.3 cu in. of air (1 f/5cc) over a standard 40-hour work week.

Asbestosis

Asbestos is a fibrous, incombustible form of magnesium and calcium silicate used in making insulating materials. By the late 1970s, over 6 million tons of asbestos were being produced worldwide. About two-thirds of the asbestos used in the United States is used in building materials, brake linings, textiles, and insulation, while the remaining one-third is consumed in such diverse products as paints, **plastics**, caulking compounds, floor tiles, cement, roofing paper, radiator covers, theater curtains, fake fireplace ash, and many other materials.

It has been estimated that of the eight to eleven million current and retired workers exposed to large amounts of asbestos on the job, 30 to 40 percent can expect to die of **cancer**. Several different types of asbestos-related diseases are known, the most significant being asbestosis. Asbestosis is a chronic disease characterized by scarring of the lung tissue. Most commonly seen among workers who have been exposed to very high levels of asbestos dust, asbestosis is an irreversible, progressively worsening disease. Immediate symptoms include shortness of breath after exertion, which results from decreased lung capacity. In most cases, extended exposure of 20 years or more must occur before symptoms become serious enough to be investigated. By this time the disease is too advanced for treatment. That is why asbestos could be referred to as a silent killer.

Exposure to asbestos not only affects factory workers working with asbestos, but individuals who live in areas surrounding asbestos emissions. In addition to asbestosis, exposure may result in a rare form of cancer called mesothelioma, which affects the lining of the lungs or stomach. Approximately 5–10% of all workers employed in asbestos manufacturing or mining operations die of mesothelioma.

Asbestosis is characterized by dyspnea (labored breathing) on exertion, a nonproductive cough, hypoxemia (insufficient oxygenation of the blood), and decreased lung volume. Progression of the disease may lead to respiratory failure and cardiac complications. Asbestos workers who **smoke** have a marked increase in the risk for developing bronchogenic cancer.

Increased risk is not confined to the individual alone, but there is an extended risk to workers' families, since asbestos dust is carried on clothes and in hair. Consequently, in the fall of 1986, President Reagan signed into law the Asbestos Hazard Emergency Response Act (AHERA), requiring that all primary and secondary schools be inspected for the presence of asbestos; if such materials are found, the school district must file, and carry out an asbestos abatement plan. The **Environmental Protection Agency** (EPA) was charged with the oversight of the project.

Ashio, Japan

Much could be learned from the Ashio, Japan, mining and smelting operation concerning the effects of **copper poison-**

ing on human beings, rice paddy soils, and the **environment**, including the comparison of long term costs and short term profits.

Copper has been mined in Japan since A.D. 709, and **pollution** has been reported since the sixteenth century. Copper leached from the Ashio Mine pit and **tailings** flowed into the Watarase River killing fish and contaminating rice paddy soils in the mountains of central Honshu. The refining process also released large quantities of sulfur oxide and other waste gases, which killed the vegetation and life in the surrounding streams. In 1790 protests by local farmers forced the mine to close, but it became the property of the government and was reopened to increase the wealth of Japan after Emperor Meiji came to power in 1869. The mine passed into private ownership in 1877, and new technological innovations were introduced to increase the mining and smelting output. A year later, signs of copper pollution were already appearing. Rice yields decreased and people who bathed in the river developed painful sores, but production expanded.

A large vein of copper ore was discovered in 1884, and by 1885 the Ashio Copper mine produced 4,100 tons, about 40% of the total national output per year. **Arsenic** was a byproduct. The piles of slag mounted, and more waste **runoff** polluted the Watarase River and local farmlands. As the crops were damaged and the fish polluted, many people became ill. Consequently, a stream of complaints was heard, and some agreements were made to pay money, not for damages as such but just to "help out" the farmers. Meanwhile, mining and smelting continued as usual. In 1896 a **tailings pond** dam gave way and the deluge of **mine spoil waste** and water contaminated 59,280 acres (24,000 ha) of farm land in six prefectures from Ashio nearly to Tokyo 93 mi (150 km) away. Then the government ordered the Ashio Mining Company to construct facilities to prevent damage by pollutants, but in times of **flooding** these were largely ineffectual. In 1907 the government forced the inhabitants of the Yanaka Village, who had been the most affected by poisoning, to move to Hokkaido, making way for a flood control project.

In 1950, as a result of the Korean War, the Ashio Copper Mine expanded production and upgraded the smelting plant to compete with the high grade ores being processed from other mines. When the Gengorozawa slag pile, the smallest of 14, collapsed and introduced 2,614 cubic yd (2,000 cubic m) of slag into the Watarase River in 1958, it contaminated 14,820 acres (6,000 ha) of rice fields. No remedial action was taken, but in 1967 a maximum average yearly standard of 0.06 mg/l copper in the river water was set. This was meaningless because most of the contamination occurred when large quantities of slag were **leaching** out during the rainy periods and floods. Japanese authorities also set 125 mg Cu/kg in paddy **soil** as the maximum allowable limit alleged not to damage rice yields, twice the minimum effect level of 56 mg Cu/kg.

In 1972 the government ordered that rice from this area be destroyed, even as the Ashio Mining Company still denied responsibility for its contamination. Testing showed that the soil of the Yanaka Village up to 10 ft (3 m) below the surface still contained 314 mg/kg of copper, 34 mg/kg of **lead**, 168 mg/kg of zinc, 46 mg/kg of arsenic, 0.7 mg/kg of **cadmium**, and 611 mg/kg of manganese. This land drains into the Watarase River, which now provides drinking water for the Tokyo metropolitan area and surrounding prefectures.

That same year the Ashio Mine announced that it was closing due to reduced demand for copper ore and worsening mining conditions; however, smelting continued with imported ores, so the slag piles still accumulated and minerals percolated to the river, especially during spring flooding. In August 1973, the Sabo dam collapsed and released about 2,000 tons of tailings into the river. Later that year the Law Concerning Compensation for Pollution Related Health Damage and Other Measures was passed, and it prompted the Environmental Agency's Pollution Adjustment Committee to begin reviewing the farmers' claims more seriously. For the first time, the company was required to admit being the source of pollution. The farmers' suit was litigated from March 1971 until May 1974, and the plaintiffs were awarded $5 million, much less than they asked for.

As major floods have been impossible to control, some efforts are being made to reforest the mountains. After they were washed bare of soil, the rocks fell and eroded, adding another hazard. So far, large expenditures have produced few results either in flood control or reforestation. The town of Ashio is now trying to attract tourism by billing the denuded mountains as the Japanese Grand Canyon, and the pollution continues.

Asian longhorn beetle

The Asian longhorn beetle (*Anoplophora glabripennis*) is classified as a **pest** in the United States and their homeland of China. The beetles have the potential to destroy millions of hardwood trees, according to the United States Department of Agriculture (USDA).

Longhorn beetles live for one year. They are 1–1.5 in (2.5–3.8 cm) long, and their backs are black with white spots. The beetles' long antennae are black and white and extend up to 1 in (2.5 cm) beyond the length of their bodies.

Female beetles chew into tree bark and lay from 35 to 90 eggs. After hatching, larvae tunnel into the tree, staying close to the sapwood, and eat tree tissue throughout the fall and winter. After pupating, adults beetles leave the tree through drill-like holes. Beetles feed on tree leaves and young bark for two to three days and then mate. The cycle of infestation continues as more females lay eggs.

Beetle activity can kill trees such as maples, birch, horse chestnut, poplar, willow, elm, ash, and black locust. According to the USDA, beetles came to the United States in wooden packaging material and pallets from China. The first beetles were discovered in 1996 in Brooklyn, New York. Other infestations were found in other areas of the state. In 1998, infestations were discovered in Chicago.

Due to efforts that included quarantines and eradication, infestations have been confined to New York and Chicago. The spread of these pests is always a concern and certain steps are being taken to prevent this, such as the dunnage being heat-treated before leaving China, developing an effective pheromone, biological control agents, and cutting down and burning infected trees. The felled trees are then replaced with ones that are not known to host the beetle. In 1999, 5.5 million dollars was allotted to help finance the detection of infested trees.

[*Liz Swain*]

Asian (Pacific) shore crab

The Asian (Pacific) shore crab (*Hemigrapsus sanguineus*) is a crustacean also known as the Japanese shore crab or Pacific shore crab. It was probably brought from Asia to the United States in ballast water. When a ship's hold is empty, it is filled with ballast water to stabilize the vessel.

The first Asian shore crab was seen in 1988 in Cape May, N.J. By 2001, Pacific shore crabs colonized the East Coast, with populations located from New Hampshire to North Carolina. Crabs live in the sub-tidal zone where low-tide water is several feet deep.

The Asian crab is 2–3 in (5–7.7 cm) wide. Shell color is pink, green, brown, or purple. There are three spines on each side of the shell. The crab has two claws and bands of light and dark color on its six legs.

A female produces 56,000 eggs per clutch. Asian Pacific crabs haves three or four clutches per year. Other crabs produce one or two clutches annually.

At the start of the twenty-first century, there was concern about the possible relationship between the rapidly growing Asian crab population and the decline in native marine populations such as the lobster population in Long Island Sound.

Asiatic black bear

The Asiatic black bear or moon bear (*Ursus thibetanus*) ranges through southern and eastern Asia, from Afghanistan and Pakistan through the Himalayas to Indochina, including most of China, Manchuria, Siberia, Korea, Japan, and Taiwan. The usual **habitat** of this bear is angiosperm forests, mixed hardwood-conifer forests, and brushy areas. It occurs in mountainous areas up to the tree-line, which can be as high as 13,000 ft (4,000 m) in parts of their Himalayan range.

The Asiatic black bear has an adult body length of 4.3–6.5 ft (1.3–2.0 m), a tail of 2.5–3.5 ft (75–105 cm), a height at the shoulder of 2.6–3.3 ft (80–100 cm), and a body weight of 110–440 lb (50–200 kg). Male animals are considerably larger than females. Their weight is greatest in late summer and autumn, when the animals are fat in preparation for winter. Their fur is most commonly black, with white patches on the chin and a crescent- or Y-shaped patch on their chest. The base color of some individuals is brownish rather than black.

Female Asiatic black bears, or sows, usually give birth to two small cubs 12–14 oz (350–400 g) in a winter den, although the litter can range from one to three. The gestation period is six to eight months. After leaving their birth den, the cubs follow their mother closely for about 2.5 years, after which they are able to live independently. Asiatic black bears become sexually mature at an age of three to four years, and they can live for as long as 33 years. These bears are highly arboreal, commonly resting in trees, and feeding on fruits by bending branches towards themselves as they sit in a secure place. They may also sleep during the day in dens beneath large logs, in rock crevices, or in other protected places. During the winter Asiatic black bears typically hibernate for several months, although in some parts of their range they only sleep deeply during times of particularly severe weather.

Asiatic black bears are omnivorous, feeding on a wide range of plant and animal foods. They mostly feed on sedges, grasses, tubers, twig buds, conifer seeds, berries and other fleshy fruits, grains, and mast (i.e., acorns and other hard nuts). They also eat insects, especially colonial types such as ants. Because their foods vary greatly in abundance during the year, the bears have a highly seasonal diet. Asiatic black bears are also opportunistic carnivores, and will also scavenge dead animals that they find. In cases where there is inadequate natural habitat available for foraging purposes, these bears will sometimes kill penned livestock, and they will raid bee hives when available. In some parts of their range, Asiatic black bears maintain territories in productive, lowland forests. In other areas they feed at higher elevations during the summer, descending to lower habitats for the winter.

All the body parts of Asiatic black bears are highly prized in traditional Chinese medicine, most particularly the gall bladders. Bear-paw soup is considered to be a delicacy in Chinese cuisine. Most bears are killed for these purposes by shooting or by using leg-hold, dead-fall, or pit traps. Some animals are captured alive, kept in cramped cages, and fitted with devices that continuously drain secretions from their gall bladder, which are used to prepare traditional medicines and tonics.

Populations of Asiatic black bears are declining rapidly over most of their range, earning them a listing of Vulnerable by the IUCN. These damages are being caused by **overhunting** of the animals for their valuable body parts (much of this involves illegal **hunting**, or **poaching**), disturbance of their forest habitats by timber harvesting, and permanent losses of their habitat through its conversion into agricultural land-use. These stresses and ecological changes have caused Asiatic black bears to become endangered over much of their range.

Assimilative capacity

Assimilative capacity refers to the ability of the **environment** or a portion of the environment (such as a stream, lake, air mass, or **soil** layer) to carry waste material without adverse effects on the environment or on users of its resources. **Pollution** occurs only when the assimilative capacity is exceeded. Some environmentalists argue that the concept of assimilative capacity involves a substantial element of value judgement, i.e., pollution **discharge** may alter the **flora** and **fauna** of a body of water, but if it does not effect organisms we value (e.g., fish) it is acceptable and within the assimilative capacity of the body of water.

A classical example of assimilative capacity is the ability of a stream to accept modest amounts of **biodegradable** waste. Bacteria in a stream utilize oxygen to degrade the organic matter (or **biochemical oxygen demand**) present in such a waste, causing the level of **dissolved oxygen** in the stream to fall; but the decrease in dissolved oxygen causes additional oxygen to enter the stream from the **atmosphere**, a process referred to as reaeration. A stream can assimilate a certain amount of waste and still maintain a dissolved oxygen level high enough to support a healthy population of fish and other aquatic organisms. However, if the assimilative capacity is exceeded, the concentration of dissolved oxygen will fall below the level required to protect the organisms in the stream.

Two other concepts are closely related: 1) critical load; and 2) self purification. The term critical load is synonymous with assimilative capacity and is commonly used to refer to the concentration or mass of a substance which, if exceeded, will result in adverse effects, i.e., pollution. Self purification refers to the natural process by which the environment cleanses itself of waste materials discharged into it. Examples include biodegradation of wastes by natural bacterial populations in water or soil, oxidation of organic **chemicals** by photochemical reactions in the atmosphere, and natural **die-off** of disease causing organisms.

Determining assimilative capacity may be quite difficult, since a substance may potentially affect many different organisms in a variety of ways. In some cases, there is simply not enough information to establish a valid assimilative capacity for a pollutant. If the assimilative capacity for a substance can be determined, reasonable standards can be set to protect the environment and the allowable waste load can be allocated among the various dischargers of the waste. If the assimilative capacity is not known with certainty, then more stringent standards can be set, which is analogous to buying insurance (i.e., paying an additional sum of money to protect against potential future losses). Alternatively, if the cost of control appears high relative to the potential benefits to the environment, a society may decide to accept a certain level of risk.

The Federal **Water Pollution** Control Amendments of 1972 established the elimination of discharges of pollution into navigable waters as a national goal. More recently, pollution prevention has been heavily promoted as an appropriate

goal for all segments of society. Proper interpretation of these goals requires a basic understanding of the concept of assimilative capacity. The intent of Congress was to prohibit the discharge of substances in amounts that would cause pollution, not to require a concentration of zero. Similarly, Congress voted to ban the discharge of toxic substances in concentrations high enough to cause harm to organisms.

Well meaning individuals and organizations sometimes exert pressure on regulatory agencies and other public and private entities to protect the environment by ignoring the concept of assimilative capacity and reducing waste discharges to zero or as close to zero as possible. Failure to utilize the natural assimilative capacity of the environment not only increases the cost of **pollution control** (the cost to the discharger and the cost to society as a whole); more importantly, it results in the inefficient use of limited resources and, by expending materials and energy for something that **nature** provides free of charge, results in an overall increase in pollution.

[*Stephen J. Randtke*]

St. Francis of Assisi (1181 – 1226)

Italian Saint and religious leader

Born the son of a cloth merchant in the Umbrian region of Italy, Giovanni Francesco Bernardone became St. Francis of Assisi, one of the most inspirational figures in Christian history. As a youth, Francis was entranced by the French troubadours, but then planned a military career. While serving in a war between Assisi and Perugia in 1202, he was captured and imprisoned for a year. He intended to return to combat when he was released, but a series of visions and incidents, such as an encounter with a leper, led him in a different direction.

This direction was toward Jesus. Francis was so taken with the love and suffering of Jesus that he set out to live a life of prayer, preaching, and poverty. Although he was not a priest, he began preaching to the townspeople of Assisi and soon attracted a group of disciples, which Pope Innocent III recognized in 1211, or 1212, as the Franciscan order. The order grew quickly, but Francis never intended to found and control a large and complicated organization. His idea of the Christian life led elsewhere, including a fruitless attempt to end the Crusades peacefully. In 1224 he undertook a 40-day fast at Mount Alverna, from which he emerged bearing stigmata—wounds resembling those Jesus suffered on the cross. He died in 1226 and was canonized in 1228.

Francis's unconventional life has made him attractive to many who have questioned the direction of their own societies. In recent years his rejection of warfare and material goods has brought him the title of "the hippie saint"; Leonardo Boff has seen him as a foreshadowing of liberation theology. Lynn White has proposed him as "a patron saint for ecologists."

There is no doubt that Francis loved **nature**. In his "Canticle of the Creatures," he praises God for the gifts, among others, of "Brother Sun," "Sister Moon," and "Mother Earth, Who nourishes and watches us..." But this is not to say that Francis was a pantheist or nature worshipper. He loved nature not as a whole, but as the assembly of God's creations. As G. K. Chesterton remarked, Francis "did not want to see the wood for the trees. He wanted to see each tree as a separate and almost a sacred thing, being a child of God and therefore a brother or sister of man."

For White, Francis was "the greatest radical in Christian history since Christ" because he departed from the traditional Christian view in which humanity stands over and against the rest of nature—a view, White charges, that is largely responsible for current ecological crises. Against this view, Francis "tried to substitute the idea of the equality of all creatures, including man, for the idea of man's limitless rule of creation."

Asthma

Asthma is a condition characterized by unpredictable and disabling shortness of breath. It features episodic attacks of bronchospasm (prolonged contractions of the bronchial smooth muscle), and is a complex disorder involving biochemical, autonomic, immunologic, infectious, endocrine, and psychological factors to varying degrees in different individuals.

Asthma occurs in families suggesting that there is a genetic predisposition for the disorder, although the exact mode of genetic transmission remains unclear. The **environment** appears to play an important role in the expression of the disorder. For example, asthma can develop when *predisposed* individuals become infected with viruses or are exposed to allergens or pollutants. On occasion foods or drugs may precipitate

an attack. Psychological factors have been investigated but have yet to be identified with any specificity.

The severity of asthma attacks varies among individuals, over time, and with the degree of exposure to the triggering factors. Approximately half of all cases of asthma develop during childhood. Another third develop before the age of 40. There are two basic types of asthma—intrinsic and extrinsic. Extrinsic asthma is triggered by allergens while intrinsic asthma is not. Extrinsic asthma, or allergic asthma, is classified as Type I or Type II, depending on the type of allergic response involved. Type I extrinsic asthma is the classic allergic asthma which is common in children and young adults who are highly sensitive to dust and pollen, and is often seasonal in nature. It is characterized by sudden, brief, intermittent attacks of bronchospasms that readily respond to bronchodilators. Type II extrinsic asthma, or allergic alviolitis, develops in adults under age 35 after long exposure to irritants. Attacks are more prolonged than Type I and are more inflammatory. Fever and infiltrates which are visible on chest x-rays often accompany bronchospasm.

Intrinsic asthma has no known immunologic cause and no known seasonal variation. It usually occurs in adults over the age of 35, many of whom are sensitive to aspirin and have nasal polyps. Attacks are often severe and do not respond well to bronchodilators.

A third type of asthma which occurs in otherwise normal individuals is called exercise induced asthma. Individuals with exercise induced asthma experience mild to severe bronchospasms during or after moderate to severe exertion. They have no other occurrences of bronchospasms when not involved in physical exertion. Although the cause of this type of asthma has not been established it is readily controlled by using a bronchodilator prior to beginning exercise.

Aswan High Dam

A heroic symbol and an **environmental liability**, this dam on the Nile River was built as a central part of modern Egypt's nationalist efforts toward modernization and industrial growth. Begun in 1960 and completed by 1970, the High Dam lies near the town of Aswan, which sits at the Nile's first cataract, or waterfall, 200 river mi (322 km) from Egypt's southern border. The dam generates urban and industrial power, controls the Nile's annual **flooding**, ensures year-round, reliable **irrigation**, and has boosted the country's economic development as its population climbed from 20 million in 1947 to 58 million in 1990. The Aswan High Dam is one of a generation of huge **dams** built on the world's major rivers between 1930 and 1970 as both functional and symbolic monuments to progress and development. It also represents the hazards of large-scale efforts to control **nature**. Altered flooding, irrigation, and **sediment** deposition patterns have led to the displacement of villagers and farmers, a costly dependence on imported **fertilizer**, **water quality** problems and health hazards, and **erosion** of the Nile Delta.

Aswan attracted international attention in 1956, when planners pointed out that flooding behind the new dam would drown a number of ancient Egyptian tombs and monuments. A worldwide plea went out for assistance in saving the 4000-year old monuments, including the tombs and colossi of Abu Simbel and the temple at Philae. The United Nations Educational and Scientific Organization (**UNESCO**) headed the epic project, and over the next several years the monuments were cut into pieces, moved to higher ground, and reassembled above the water line.

The High Dam, built with international technical assistance and substantial funding from the former Soviet Union, was the second to be built near Aswan. English and Egyptian engineers built the first Aswan dam between 1898 and 1902. Justification for the first dam was much the same as that for the second, larger dam, namely flood control and irrigation. Under natural conditions the Nile experienced annual floods of tremendous volume. Fed by summer rains on the Ethiopian Plateau, the Nile's floods could reach 16 times normal low season flow. These floods carried terrific **silt** loads, which became a rich fertilizer when flood waters overtopped the river's natural banks and sediments settled in the lower surrounding fields. This annual soaking and fertilizing kept Egypt's agriculture prosperous for thousands of years. But annual floods could be wildly inconsistent. Unusually high peaks could drown villages. Lower than usual floods might not provide enough water for crops. The dams at Aswan were designed to eliminate the threat of high water and ensure a gradual release of irrigation water through the year.

Flood control and regulation of irrigation water supplies became especially important with the introduction of commercial cotton production. Cotton was introduced to Egypt by 1835, and within 50 years it became one of the country's primary economic assets. Cotton required dependable water supplies, but with reliable irrigation up to three crops could be raised in a year. Full-year commercial cropping was an important economic innovation, vastly different from traditional seasonal agriculture. By holding back most

An aerial view of the Aswan High Dam in Egypt. (Corbis-Bettmann. Reproduced by permission.)

of the Nile's annual flood, the first dam at Aswan captured 65.4 billion cubic yd (50 billion cubic m) of water each year. Irrigation canals distributed this water gradually, supplying a much greater acreage for a much longer period than did natural flood irrigation and small, village-built water works. But the original Aswan dam allowed 39.2 billion cubic yd (30 billion cubic m) of annual flood waters to escape into the Mediterranean. As Egypt's population, agribusiness, and development needs grew, planners decided this was a loss that the country could not afford.

The High Dam at Aswan was proposed in 1954 to capture escaping floods and to store enough water for long-term **drought**, something Egypt had seen repeatedly in history. Three times as high and nearly twice as long as the original dam, the High Dam increased the reservoir's storage capacity from an original 6.5 billion cubic yd (5 billion cubic m) to 205 billion cubic y (157 billion cubic m). The new dam lies 4.3 mi (7 km) upstream of the previous dam, stretches 2.2 mi (3.6 km) across the Nile and is nearly 0.6 mi (1 km) wide at the base. Because the dam sits on sandstone, gravel, and comparatively soft sediments, an impermeable screen of concrete was injected 590 ft (180 m) into the rock, down to a buried layer of granite. In addition to increased storage and flood control, the new project incorporates a hydropower generator. The dam's turbines, with a capacity of 8 billion kilowatt hours per year, doubled Egypt's electricity supply when they began operation in 1970.

Lake Nasser, the **reservoir** behind the High Dam, now stretches 311 mi (500 km) south to the Dal cataract in Sudan. Averaging 6.2 mi (10 km) wide, this reservoir holds the Nile's water at 558 ft (170 m) above sea level. Because this reservoir lies in one of the world's hottest and driest regions, planners anticipated evaporation at the rate of 13 cubic yd (10 billion cubic m) per year. Dam engineers also planned for **siltation**, since the dam would trap nearly all the sediments previously deposited on downstream flood plains. Expecting that Lake Nasser would lose about 5% of its volume to siltation in 100 years, designers anticipated a volume loss of 39.2 billion cubic yd (30 billion cubic m) over the course of five centuries.

An ambitious project, the Aswan High Dam has not turned out exactly according to sanguine projections. Actual evaporation rates today stand at approximately 19 billion cubic

yd (15 billion cubic m) per year, or half of the water gained by constructing the new dam. Another 1.3–2.6 cubic yd (1–2 billion cubic m) are lost each year through **seepage** from unlined irrigation canals. Siltation is also more severe than expected. With 60–180 million tons of silt deposited in the lake each year, current projections suggest that the reservoir will be completely filled in 300 years. The dam's effectiveness in flood control, water storage, and power generation will decrease much sooner. With the river's silt load trapped behind the dam, Egyptian farmers have had to turn to chemical fertilizer, much of it imported at substantial cost. While this strains commercial **cash crop** producers, a need for fertilizer application seriously troubles local food growers who have less financial backing than agribusiness ventures.

A further unplanned consequence of silt storage is the gradual disappearance of the Nile Delta. The Delta has been a site of urban and agricultural settlement for millennia, and a strong local fishing industry exploited the large schools of sardines that gathered near the river's outlets to feed. Longshore currents sweep across the Delta, but annual sediment deposits counteracted the erosive effect of these currents and gradually extended the delta's area. Now that the Nile's sediment load is negligible, coastal erosion is causing the Delta to shrink. The sardine fishery has collapsed, since river **discharge** and **nutrient** loads have been so severely depleted. Decreased fresh water flow has also cut off water supply to a string of fresh water lakes and underground aquifers near the coast. Salt water **infiltration** and **soil salinization** have become serious threats.

Water quality in the river and in Lake Nasser have suffered as well. The warm, still waters of the reservoir support increasing concentrations of **phytoplankton**, or floating water plants. These plants, most of them microscopic, clog water intakes in the dam and decrease water quality downstream. Salt concentrations in the river are also increasing as a higher percentage of the river's water evaporates from the reservoir.

While the High Dam has improved the quality of life for many urban Egyptians, it has brought hardship to much of Egypt's rural population. Most notably, severe health risks have developed in and around irrigation canal networks. These canals used to flow only during and after flood season; once the floods dissipated the canals would again become dry. Now that they are full year round, irrigation canals have become home to a common tropical snail that carries **schistosomiasis**, a debilitating disease that severely weakens its victims. **Malaria** may also be spreading, since moist mosquito breeding spots have multiplied. Farm fields, no longer washed clean each year, are showing high salt concentrations in the soil. Perhaps most tragic is the displacement of villagers, especially Nubians, who are ethnically distinct from their northern Egyptian neighbors and who lost most of their villages to Lake Nasser. Resettled in apartment blocks and forced to find work in the cities, Nubians are losing their traditional culture.

The Aswan High Dam was built as a symbol of national strength and modernity. By increasing industrial and agricultural output the dam generates foreign exchange for Egypt, raises the national standard of living, and helps ensure the country's high status and profile in international affairs. For all its problems, Lake Nasser now supports a fishing industry that partially replaces jobs lost in the delta fishery, and tourists contribute to the national income when they hire cruise boats on the lake. Most important, the country's expanded population needs a great deal of water. The Egyptian population is currently at 68 million but projected at 90 million by the year 2035, and neither the people nor their necessary industrial activity could survive on the Nile's natural meager water supply in the dry season. The Aswan dam was built during an era when dams of epic scale were appearing on many of the world's major rivers. Such projects were a cornerstone of development theory at the time, and if most rivers were not already dammed today, huge dams might still be central to development theory. Like other countries, including the United States, Egypt experiences serious problems and threats of future problems in its dam, but the Aswan dam is a central part of life and planning in modern Egypt.

Atmosphere

The atmosphere is the envelope of gas surrounding the earth, which is for the most part permanently bound to the earth by the gravitational field. It is composed primarily of **nitrogen** (78% by volume) and oxygen (21%). There are also small amounts of argon, **carbon dioxide**, and water vapor, as well as trace amounts of other gases and **particulate** matter.

(Illustration by Hans & Cassidy.)

Trace components of the atmosphere can be very important in atmospheric functions. **Ozone** accounts on average for two **parts per million** of the atmosphere but is more concentrated in the **stratosphere**. This stratospheric ozone is critical to the existence of terrestrial life on the planet. Particulate matter is another important trace component. **Aerosol loading** of the atmosphere, as well as changes in the tiny **carbon** dioxide component of the atmosphere, can be responsible for significant changes in **climate**.

The composition of the atmosphere changes over time and space. Outside of water vapor (which can vary from 0–4% in the local atmosphere) the concentrations of the major components varies little in time. Above 31 mi (50 km) from sea level, however, the relative proportions of component gases change significantly. As a result, the atmosphere is divided into two compositional components: Below 31 mi (50 km) is the homisphere and above 31 mi (50 km) is the heterosphere.

The atmosphere is also divided according to its thermal behavior. By this criteria, the atmosphere can be divided into several layers. The bottom layer is the *troposphere*; it contains most of the atmosphere and is the domain of weather. Above the **troposphere** is a stable layer called the stratosphere. This layer is important because it contains much of the ozone which **filters** ultraviolet light out of the incident solar radiation. The next layer, is the *mesosphere*, which is much less stable. Finally, there is the *thermosphere*; this is another very stable zone, but its contents are barely dense enough to cause a visible degree of solar radiation scattering.

Atmospheric (air) pollutants

Atmospheric pollutants are substances that accumulate in the air to a degree that is harmful to living organisms or to materials exposed to the air. Common air pollutants include **smoke**, **smog**, and gases such as **carbon monoxide**, **nitrogen** and sulfur oxides, and hydrocarbon fumes. While gaseous pollutants are generally invisible, solid or liquid pollutants in smoke and smog are easily seen. One particularly noxious form of **air pollution** occurs when oxides of sulfur and nitrogen combine with atmospheric moisture to produce sulfuric and nitric **acid**. When the acids are brought to Earth in the form of **acid rain**, damage is inflicted on lakes, rivers, vegetation, buildings, and other objects. Because sulfur and **nitrogen oxides** can be carried for long distances in the **atmosphere** before they are removed in precipitation, damage may occur far from **pollution** sources.

Smoke is an ancient environmental pollutant, but increased use of **fossil fuels** in recent centuries has increased its severity. Smoke can aggravate symptoms of **asthma**, **bronchitis**, and **emphysema**, and long term exposure can lead to lung **cancer**. Smoke toxicity increases when fumes of **sulfur dioxide**, commonly released by **coal combustion**, are inhaled with it. One particularly bad air pollution incident occurred in London in 1952 when approximately 4,000 deaths resulted from high smoke and sulfur dioxide levels that accumulated in the metropolitan area during an **atmospheric inversion**.

Sources of air pollutants are particularly abundant in modem, industrial population centers. Major sources include power and heating plants, industrial manufacturing plants, and **transportation** vehicles. Mexico City is a particularly bad example of a very large metropolitan area that has not adequately controlled harmful emissions into the atmosphere, and as a result many area residents suffer from respi-

ratory ailments. The Mexican government has been forced to shut down a large oil refinery and ban new polluting industries from locating in the city. More difficult for the Mexican government to control are the emissions from over 3.5 million automobiles, trucks, and buses.

Smog (a combination of smoke and fog) is formed from the condensation of moisture (fog) on **particulate** matter (smoke) in the atmosphere. Although smog has been present in urban areas for a long time, **photochemical smog** is an exceptionally harmful and annoying form of air pollution found in large urban areas. It was first recognized as a serious problem in Los Angeles in the late 1940s. Photochemical smog forms by the catalytic action of sunlight on some atmospheric pollutants including unburned **hydrocarbons** evaporated from **automobile** and other fuel tanks. Products of the photochemical reactions include **ozone**, aldehydes, **ketones**, **peroxyacetyl nitrate**, and organic acids. Photochemical smog causes serious eye and lung irritation and other health problems.

Because of the serious damage caused by atmospheric pollution, control has become a high priority in many countries. Several approaches have proven beneficial. An immediate control measure involves a system of air alerts announced when air pollution monitors disclose dangerously high levels of contamination. Industrial sources of pollution are forced to curtail activities until conditions return to normal. These emergency situations are often caused by atmospheric inversions that limit the upward mixing of pollutants. Wider dispersion of pollutants by taller smokestacks can alleviate local pollution. However, dispersion does not lessen overall amounts; instead, it can create problems for communities downwind from the source. Greater **energy efficiency** in vehicles, homes, electrical **power plants**, and industrial plants, lessens pollution from these sources. This reduction in fuel use also reduces pollution created when fuels are produced, and as an added benefit, more energy efficient operation reduces costs. Efficient and convenient **mass transit** also helps to mitigate urban air pollution by cutting the need for personal vehicles.

Atmospheric deposition

Many kinds of particulates and gases are deposited from the **atmosphere** to the surfaces of terrestrial and aquatic ecosystems. Wet deposition refers to deposition occurring while it is raining or snowing, whereas **dry deposition** occurs in the time intervals between precipitation events.

Relatively large particles suspended in the atmosphere, such as dust entrained by strong winds blowing over fields or emitted from industrial smokestacks, may settle gravitationally to nearby surfaces at ground level. Particulates smaller than about 0.5 microns in diameter, however, do not settle in this manner because they behave aerodynamically like gases. Nevertheless, they may be impaction-filtered from the atmosphere when an air mass passes through a physically complex structure. For example, the large mass of foliage of a mature conifer forest provides an extremely dense and complex surface. As such, a conifer canopy is relatively effective at removing particulates of all sizes from the atmosphere, including those smaller than 0.5 microns. Forest canopies dominated by hardwood (or angiosperm) trees are also effective at doing this, but somewhat less-so than conifers.

Dry deposition also includes the removal of certain gases from the atmosphere. For example, **carbon dioxide** gas is absorbed by plants and fixed by **photosynthesis** into simple sugars. Plants are also rather effective at absorbing certain gaseous pollutants such as **sulfur dioxide**, nitric oxide, **nitrogen** dioxide, and **ozone**. Most of this gaseous uptake occurs by **absorption** through the numerous tiny pores in leaves known as stomata. These same gases are also dry-deposited by absorption by moist **soil**, rocks, and water surfaces.

Wet deposition involves substances that are dissolved in rainwater and snow. In general, the most abundant substances dissolved in precipitation water are sulfate, nitrate, calcium, magnesium, and ammonium. At places close to the ocean, sodium and chloride derived from sea-salt aerosols are also abundant in precipitation water. Acidic precipitation occurs whenever the concentrations of the anions (negatively charged ions) sulfate and nitrate occur in much larger concentrations than the cations (positively charged ions) calcium, magnesium, and ammonium. In such cases, the cation "deficit" is made up by **hydrogen** ions going into solution, creating solutions that may have an acidity less than **pH** 4. (Note that the **ion** concentrations in these cases are expressed in units of equivalents, which are molar concentrations multiplied by the number of charges on the ion.)

The deposition of acidified snow or rain can result in the **acidification** of vulnerable surface waters. This is particularly the case of streams, rivers, ponds, and lakes that have low concentrations of alkalinity and consequently little capacity for neutralizing inputs of acidity. Acidification may also be caused by the dry deposition of certain gases, especially sulfur dioxide and oxides of nitrogen. After they are dry-deposited, these gases become oxidized in soil or water into the ions sulfate and nitrate, respectively, a process accompanied by the production of equivalent amounts of hydrogen ions. In some environments the gaseous concentrations of sulfur dioxide and oxides of nitrogen are relatively high, particularly in areas polluted by gaseous emissions from large numbers of automobiles, **power plants**, or other industries. In those circumstances the dry deposition of acidifying substances will be a much more important cause of environmental acidification than the wet deposition of acidic precipitation.

Atmospheric inversion

Atmospheric inversions are horizontal layers of air that increase in temperature with height. Such warm, light air often lies over air that is cooler and heavier. As a result the air has a strong vertical **stability**, especially in the absence of strong winds.

Atmospheric inversions play an important role in **air quality**. They can trap air pollutants below or within them, causing high concentrations in a volume of air that would otherwise be able to dilute air pollutants throughout a large portion of the **troposphere**.

Atmospheric inversions are quite common, and there are several ways in which they are formed. Surface inversions can form during the evening when the radiatively cooling ground becomes a heat sink at the bottom of an air mass immediately above it. As a result heat flows down through the air which sets up a temperature gradient that coincides with an inversion. Alternatively, relatively warm air may flow over a cold surface with the same results.

Elevated atmospheric inversions can occur when vertical differences in wind direction allow warm air to set up over cold air. However, it is more common in near-subtropical latitudes, especially on the western sides of continents, to get subtropical **subsidence** inversions. Subtropical subsidence inversions often team with mountainous **topography** to trap air both horizontally and vertically. This is the situation on the coast of southern and central California.

Atomic Energy Commission

The Atomic Energy Commission (AEC) was established by act of the United States Congress in 1946. It originally had a dual function: to promote the development of **nuclear power** and to regulate the nuclear power industry. These two functions were occasionally in conflict, however. Critics of the AEC claimed that the Commission sometimes failed to apply appropriate safety regulations, for example, because doing so would have proved burdensome to the industry and hindered its growth. In 1975, the AEC was dissolved. Its regulatory role was assigned to the **Nuclear Regulatory Commission** and its research and development role to the **Energy Research and Development Administration**.

Atrazine

Atrazine is used as a selective preemergent **herbicide** on crops, including corn, sorghum, and sugar cane, and as a nonselective herbicide along fence lines, right-of-ways, and road sides. It is used in a variety of formulations, both alone and in combination with other herbicides. In the United States it is the single most widely used herbicide, accounting for about 15% of total herbicide application by weight. Its popularity stems from its effectiveness, its selectivity (it inhibits **photosynthesis** in plants lacking a **detoxification** mechanism), and its low mammalian toxicity (similar to that of table salt). Concern over its use stems from the fact that a small percentage of the amount applied can be carried by rainfall into surface waters (stream and lakes), where it may inhibit the growth of plants and algae or contaminate **drinking-water supply**. Because atrazine is classified as a possible human **carcinogen**, the United States **Environmental Protection Agency** (EPA) has limited its concentration in drinking water to 3 μg/L.

Attainment area

An attainment area is a politically or geographically defined region that is in compliance with the National Ambient Air Quality Standards, as set by the **Environmental Protection Agency** (EPA). A region is considered to be an attainment area if it does not exceed the specified thresholds for air pollutants that may be a threat to public health. The standards are set for a variety of ambient air pollutants, including particulates, **ozone**, **carbon monoxide**, sulfur oxides, and **nitrogen oxides**. A region can be an attainment area for one pollutant and a **nonattainment area** for another.

John James Audubon (1785 – 1851)

American naturalist, artist, and ornithologist

John James Audubon, the most renowned artist and naturalist in nineteenth century America, left a legacy of keenly observant writings as well as a portfolio of exquisitely rendered paintings of the birds of North America.

Born April 26, 1785, Audubon was the illegitimate son of a French naval captain and a domestic servant girl from Santo Domingo (now Haiti). Audubon spent his childhood on his father's plantation in Santo Domingo and most of his late teens on the family estate in Mill Grove, Pennsylvania—a move intended to prevent him from being conscripted into the Napoleonic army.

Audubon's early pursuits centered around natural history, and he was continuously collecting and drawing plants, insects, and birds. His habit of keeping meticulous field notes of his observations at a young age. It was at Mill Grove that Audubon, in order to learn more of the movements and habits of birds, tied bits of colored string onto the legs of several Eastern Phoebes and so proved that these birds returned to the same nesting sites the following year. Audubon was the first to use banding to study the movement of birds.

While at Mill Grove, Audubon began courting their neighbor's eldest daughter, Lucy Bakewell, and they were married in 1808. They made their first home in Louisville, Kentucky, where Audubon tried being a storekeeper. He could not stand staying inside, and so he spent most of his time afield to "supply fowl for the table," thus dooming the store to failure.

In 1810, Audubon met by chance Alexander Wilson, who is considered the father of American ornithology. Wilson had finished much of his nine volume *American Ornithology* at this time, and it is believed that his work inspired Audubon to embark on his monumental task of painting the birds of North America.

The task that Audubon undertook was to become *The Birds of America*. Because Audubon decided to depict each **species** of bird life-size, thus rendering each on a 36.5 in x 26.5 in (93 cm x 67 cm) page, this was the largest book ever published up until that time. He was able to draw even larger birds such as the **whooping crane** life-size by depicting them with their heads bent to the ground. Audubon pioneered the use of fresh models instead of stuffed museum skins for his paintings. He would shoot birds and wire them into life-like poses to obtain the most accurate drawings possible. Even though his name is affixed to a modern **conservation** organization, the **National Audubon Society**, it must be remembered that little thought was given to the conservation of birds in the early nineteenth century. It was not uncommon for Audubon to shoot a dozen or more individuals of a species to get what he considered the perfect one for painting.

Audubon solicited subscribers for his *Birds of America* to finance the printing and hand-coloring of the plates. The project took nearly twenty years to complete, but the resulting double elephant folio, as it is known, was truly a work of art, as well as the ornithological triumph of the time. Later in his life, Audubon worked on a book of the mammals of North America with his two sons, but failing health forced him to let them complete the work. He died in 1851, leaving behind a remarkable collection of artwork that depicted the natural world he loved so much.

Australia

The Commonwealth of Australia, a country in the South Pacific Ocean, occupies the smallest continent and covers an area of 2,966,200 mi^2 (7,682,000 km^2). Along the northeast coast of Australia, for a distance of 1,200 mi (2,000 km) in length and offshore as much as 100 mi (160 km) into the Pacific Ocean, lies the **Great Barrier Reef**, the greatest assemblage of coral reefs in the world. The island of Tasmania, which is a part of Australia, lies off the southeast coast of the mainland. Australia consists mainly of plains and plateaus, most of which average 2,000 ft (600 m) above sea level. There are several low mountain ranges in the country. Only about 16 million people live in Australia, of whom about 150,000 are native people, the Aborigines.

More than a third of Australia receives under 10 in (25 cm) of annual rainfall, while less than a third receives over 20 in (51 cm). Many areas experience prolonged **drought** and frequent heat waves. The Outback is one such area. It is comprised of dry, barren land and vast interior deserts. Soils generally are poor, with fertile land found only in the lowlands and valleys near the east and southeast coast. The largest river is the Murray River in southeastern Australia. In the inland area, few rivers have much water due to the lack of rainfall. In areas with coastal highlands, rivers flow only a short distance to the sea. Lakes frequently dry up and become beds of salt. In contrast, there are lush rain forests in the north and snowy mountains in the southeastern Blue Range.

The most common tree is the eucalyptus, of which there are at least 600 different kinds. Since Australia is the driest of the inhabited continents, there are few forests. The acacia, or wattle, is Australia's national flower. Many of the mammals of Australia (kangaroos, wallabies, and koala bears) are marsupials, unlike those found anywhere else in the world. The young of marsupials are born premature and require continued development outside the womb in pouches on the parent's body. The egg-laying mammal, or monotreme, is also only found in Australia. There are two **species** of monotreme: the duck-billed platypus and the echidna, or spiny anteater. The most famous Australian bird is the kookaburra. There are no hoofed animals in Australia. Two flightless birds, the emu and the cassowary, also are found only in Australia. Snakes are common and include many poisonous species. Two kinds of **crocodiles** are found in the northern part of Australia. All of these unique **fauna** and **flora** species have evolved due to the long separation of the Australian continent from southeast Asia and a general lack of predators.

The goal of environmental protection and management in Australia is integration of the principles of ecologically **sustainable development** into policies and programs encompassing all aspects of environmental issues.

Australia's land resources form the basis of its unique natural heritage and its agricultural industry. However, problems of land degradation are widespread. Land degradation due to dryland **salinity** is a national problem that threatens both **biodiversity** and agricultural productivity. Dryland salinity affects about 5,434,000 acres (2.2 million ha) of once-productive agricultural land and costs an estimated $243 million per year in lost agricultural production. Dryland salinity originates from salt deposited in the landscape over millions of years due to marine **sedimentation**. Land clearing over the last two hundred years and the replacement of deep-rooted perennial native vegetation with shallow-rooted

annuals have caused water tables to rise, bringing saline water close to the surface into the root zones of plants. Excessive **irrigation** has also led to increases in levels of water tables. Strategies to address this problem include research for the prediction, prevention, and reversal of dryland salinity. An example of a research effort to ameliorate the effects of salinity is a project that addresses the identification of salt-tolerant plant species and development of appropriate establishment and growth management techniques to ensure their survival. Australia's naturally fire-adapted **ecosystem** has frequent brushfires that now threaten many new developments and even major cities. Other land degradation problems being addressed include the **rehabilitation** of mining sites and **remediation** of sites contaminated by railway operations.

Australia contains about 10% of the world's biological diversity. The Commonwealth is addressing the issues of loss of biodiversity through a program referred to as the National Vegetation Initiative (NVI). About 988 million acres (40 million ha) of land is protected within a terrestrial reserves system, but 1,235 million acres (500 million ha), or more than two-thirds of Australia's land area, are managed by private landholders. Biodiversity outside the reserves has been affected by vegetation clearance and modification. The NVI will attempt to reverse the long-term decline in the quality and extent of Australia's native vegetation by developing programs and incentives to conserve, enhance, and manage remnant native vegetation; to increase revegetation activities; and to encourage the integration of native vegetation into conventional farming systems.

The state of Australia's rivers and other aquatic systems has been declining due to a range of factors. Unsustainable water extractions for agricultural production have resulted in reduced flows in rivers that result in blue-green algae outbreaks, declines in native fish populations, increases in salinity, loss of **wetlands**, and loss of the beneficial aspects of small floods. Research is being conducted to define environmental flow requirements so that water allocations or entitlements will include environmental needs as a legitimate use. Other factors affecting the decline in aquatic systems include poor land and vegetation management, agricultural and urban **pollution**, salinity, destruction of native **habitat**, and spread of exotic pests such as the European carp and the water weed *Salvinia*.

In a 1997 Australian Bureau of **Statistics** survey, the Australian people identified **air pollution** as their greatest environmental concern. The government's primary **air quality** objective is to provide all Australians with equivalent protection from air pollution, which will be achieved by the development of national air quality strategies and standards that minimize the adverse environmental impacts of air pollution. Since over 60% of the Australian population lives in cities, the Government's first priority is to develop measures to reduce the impact of air pollution on urban areas.

The government of Australia considers **climate** changes as another of its most important environmental issues. A National Greenhouse Response Strategy was adopted in 1992 to respond to the need for greenhouse gas **emission** mitigation. The major thrust of the program is to develop cooperative agreements with industry to abate and reduce greenhouse gas emissions. In addition, large scale vegetation plantings for improvement of land resources will reduce **carbon dioxide**, a major greenhouse gas, in the **atmosphere**. **Methane** emission from intensive agriculture will be reduced through livestock waste treatment. The use of alternative transport fuels such as liquefied **petroleum** gas, compressed **natural gas**, **ethanol**, and other alcohol blends will be encouraged through the use of a fuel excise exemption.

Although **ozone layer depletion** in the atmosphere occurs over most of the Earth, the most dramatic changes are seen when an **ozone** "hole" forms over **Antarctica** each spring. The ozone layer protects life on Earth from harmful **ultraviolet radiation** from the sun, but it can be depleted by the use of some widely used ozone-depleting **chemicals**. The ozone hole sometimes drifts over Australia and exposes residents to dangerous levels of UV radiation. Australia, because of its proximity to Antarctica, has taken a leading role in ozone protection and has been influential in the development and implementation of cost-effective mechanisms to ensure the phase-out of use of ozone-depleting substances by all countries. The government also monitors solar ultraviolet radiation levels and assesses the consequences for public health.

Australia's marine and coastal environments are rich in natural and cultural resources, are adjacent to most of the nation's population (about 86%), and are a focus of much of Australia's economic, social, tourism, and recreational activity. Australia's **Exclusive Economic Zone** (EEZ) is one of the largest in the world, comprising 4.25 million mi^2 (11 million km^2) of marine waters. Uncoordinated and ad hoc development has been identified as a major contributing factor to the decline of coastal **water quality** and marine and estuarine habitats. Programs that include cooperation of the Commonwealth government with state and local governments, industry groups, nongovernmental organizations, and the community have been developed to protect and rehabilitate these environments. These programs include addressing threats to coastal water quality and marine biodiversity from land-based and **marine pollution**; developing integrated management plans for the **conservation** and sustainable use of coastal resources, including fisheries resources; supporting capital works and improvement of technologies to reduce the impacts of sewage and stormwater;

controlling the introduction and spread of exotic marine pests in Australian waters; protecting and restoring fish habitats; and supporting comprehensive and consistent coastal monitoring.

The Great Barrier Reef is facing growing pressures from the reef-based tourism industry, commercial and recreational fishing (which is worth about $1.3 billion per year), expanding coastal urban areas, and downstream effects of **land use** from agricultural activities. Several programs are being developed and implemented to ensure that activities can continue on an ecologically sustainable basis. For example, tourist and recreational impacts are being reduced while providing diverse tourist activities. Fishing catches and efforts are being monitored, major or critical habitats are being identified, and fishing by-catch is being reduced through the development of new methods. **Sediment**, **nutrient**, and other land-based **runoff** that impacts the health of adjacent marine areas are being controlled in coastal developments. Also, spill contingency planning and other responses to prevent pollution from ships, navigational aids, and ship reporting systems are all being improved. In addition, the state of water quality is being monitored in long-term programs throughout the Reef and threats from pollution are being assessed. Finally, all planning exercises include consultation with Aboriginal and Torres Strait Islander (ATSI) communities to ensure that their interests are considered.

The Commonwealth, through its National and World Heritage programs, is protecting elements of Australia's natural and cultural heritage that are of value for this and **future generations**. The National Estate comprises natural, historic, and indigenous places that have aesthetic, historic, scientific or social significance or other special value. The Register of the National Estate by 1997 had 11,000 places listed. The Register educates and alerts Australians to places of heritage significance. World Heritage properties are areas of outstanding universal cultural or national significance that are included in the **UNESCO** World Heritage List. In 1997, there were 11 Australian properties on the World Heritage List, including the Great Barrier Reef.

Resources
Books

Hill, R. *Investing in Our Natural Heritage*. Canberra, Australia: Annual Report on the Commonwealth's Environment Expenditure, Minister for the Environment, 1997.

Autecology

A branch of **ecology** emphasizing the interrelationships among individual members of the same **species** and their **environment**. Autecology includes the study of the life history and/or behavior of a particular species in relation to the environmental conditions that influence its activities and distribution. Autecology also includes studies on the tolerance of a species to critical physical factors (e.g., temperature, **salinity**, oxygen level, light) and biological factors (e.g., predation, **symbiosis**) thought to limit its distribution. Such data are gathered from field measurement or from controlled experiments in the laboratory. Autecology contrasts with *synecology*, the study of interacting groups (i.e., communities) of species.

Automobile

The development of the automobile at the end of the nineteenth century fundamentally changed the structure of society in the developed world and has had wide-ranging effects on the **environment**, the most notable being the increase of **air pollution** in cities. The piston-type internal **combustion** engine is responsible for the peculiar mix of pollutants that it generates. There are a range of other engines suitable for automobiles, but they have yet to displace engines using rather volatile **petroleum** derivatives.

The simplest and most successful way of improving gaseous emissions from automobiles is to find alternative fuels. Diesel fuels have always been popular for larger vehicles, although a few private vehicles in Europe are also diesel-powered. Compressed natural gases have been widely used as fuel in some countries (e.g., New Zealand), while **ethanol** has had a limited success in places such as Brazil, where it can be produced relatively cheaply from sugar cane. There is some enthusiasm for the use of **methanol** in the United States, but it has yet to be seen if this will be widely adopted as a fuel.

Others have suggested that fundamental changes to the engine itself can lower the impact of automobiles on **air quality**. The Wankel rotary engine is a promising power source that offers both low vibration and pollutant emissions from a relatively lightweight engine. Although Wankel engines are found on a number of exotic cars, there are still doubts about long-term engine performance and durability in the urban setting. Steam and gas turbines have many of the advantages of the Wankel engine, but questions of their expense and suitability for automobiles have restricted their use. Electric vehicles have had some impact for special sectors of the market. They have proved ideal for small vehicles within cities where frequent stop-start operation is required (e.g., delivery vans). A few small, one-seat vehicles have been available at times, but they have failed to achieve any enduring popularity. The electric vehicle suffers from low range, low speed and acceleration, and needs heavy batteries. However these vehicles produce none of the conventional

combustion-derived pollutants during operation, although the electricity to recharge the batteries requires the use of an electricity generating station. Still, electricity generation can be sited away from the urban center and employ air **pollution** controls. **Fuel cells** are an alternate source of electricity for electric automobiles. It is also possible to power automobiles through the use of flywheels. These are driven up to high speeds by a fixed, probably electric, motor, then the vehicle can be detached and powered using the stored momentum, although range is often limited.

Although **automobile emissions** are of great concern, the automobile has a far wider range of environmental impacts. Large amounts of material are used in their construction, and discarded automobiles can litter the countryside and fill waste dumps. Through much of the twentieth century the vehicles have been made of steel. Increasingly, other materials, such as **plastics** and fiberglass, are used as construction materials. A number of projects, most frequently on the European continent, have tried **recycling** automobile components. Responsible automobile manufacturers are aiming to build vehicles with longer road lives, further aiding **waste reduction**.

The high speeds now possible for automobiles lead to sometimes horrendous accidents, which can involve many vehicles on crowded highways. The number of accidents have been reduced through anti-lock braking systems, thoughtful road design, and imposing harsh penalties for drunk driving. In the future, on-board radar may give warning of impending collisions. Safety features such as seat belts, padding, and collapsible steering columns have helped lower injury during accidents.

The structure of cities has changed with widespread automobile ownership. It has meant that people can live further away from where they work or shop. The need for parking has led to the development of huge parking lots within the inner city. Reaction to crowding in city centers are seen in the construction of huge shopping centers out-of-town, where parking is more convenient (or strip development of large stores along highways). These effects have often caused damage to inner city life and disenfranchised non-car owners, particularly because a high proportion of car ownership often works against the operation of an effective **mass transit** system. For people who live near busy roads, **noise pollution** can be a great nuisance. The countryside has also been transformed by the need for super highways that cope with a large and rapid traffic flow. Such highways have often been built on valuable agricultural land or natural habitats, and once constructed, create both practical and aesthetic nuisances.

Environmental Effects of Automotive Emissions. Paris: OECD Compass Project, 1986.

Automobile emissions

The **automobile**, powered by piston-type internal **combustion** engine, is so widely used that it has become the dominant source of air pollutants, particularly of **photochemical smog**, in large, urban cities.

Modern internal combustion engines operate through the Otto cycle, which involves rapid batch-burning of **petroleum** vapors. The combustion inside the cylinder is initiated by a spark and proceeds outward through the gas volume until it reaches the cylinder walls where it is cooled. Close to the cylinder wall, where combustion is quenched, a fraction of the fuel remains unburnt. In the next cycle of the engine the hot combusted gases and unburnt fuel vapor are forced out through the exhaust system of the automobile.

Automotive engines generally operate on "fuel rich" mixtures, which means that there is not quite enough oxygen to completely burn the fuel. As a result there is an excess of unburnt **hydrocarbons**, particularly along the cylinder walls, and substantial amounts of **carbon monoxide**. This efficient production of **carbon** monoxide has made automobiles the most important source of this poisonous gas in the urban **atmosphere**.

The high **emission** levels of hydrocarbons and carbon monoxide have caused some engineers to become interested in "lean burn" engines that make more oxygen available during combustion. While such an approach is possible, the process also produces high concentrations of nitric oxide in the exhaust gases.

When the fuel enters the cylinder of an automobile engine in the gaseous form, it generally does not produce **smoke**. However in diesel engines where the fuel is sprayed into the combustion chamber, it will become dispersed as tiny droplets. Sometimes, especially under load, these droplets will not burn completely and are reduced to fine carbon particles, or soot, that are easily visible from diesel exhausts. In many cities this diesel smoke can represent the principle soiling agent in the air. In addition, soot, particularly those from diesel engines, contain small amounts of carcinogenic material.

Many of the carcinogens found in the exhaust from diesel engines are **polycyclic aromatic hydrocarbons** (PAH) and are archetypical carcinogens. Best known of these is benzo-a-pyrene, which was tentatively recognized as a **carcinogen** in the eighteenth century from observations of chimney sweepers who had high incidence of **cancer**.

Some of the PAH can become nitrated during combustion and these may be even more carcinogenic than the unnitrated PAH. Diesel emissions may pose a greater cancer risk than the exhaust gases from **gasoline** engines. There are a number of emissions from gasoline engines that are potentially carcinogenic. **Benzene** represents a large part of the total volatile organic emissions from automobiles. Yet the compound is also recognized by many as imposing a substantial carcinogenic risk to modern society. **Toluene**, although by no means as carcinogenic as benzene, is also emitted in large quantities. Toluene proves a very effective compound at initiating photochemical **smog** and also reacts to form the eye irritant peroxybenzoyl nitrate. The highly dangerous compound **dioxin** can be produced in auto exhausts where **chlorine** is present (anti-knock agents often contain chlorine). Formaldehyde, a suspected carcinogen, is produced in photochemical smog but may also be an enhanced risk from engines burning the otherwise less polluting **methanol** as a fuel.

Many exotic elements that are added to improve the performance of automotive fuels produce their own emissions. The best known is the anti-knock agent **tetraethyl lead**, which was added in such large quantities that it became the dominant source of **lead** particles in the air. A wide range of long-term health effects, such as lowering IQ, have been associated with exposure to lead. Although lead in urban populations are still rather high, the use of unleaded gasoline have decreased the problem somewhat.

Most attention usually focuses on the engine as a source of automobile emissions, but there are other sources. Evaporative loss of volatile materials from the crank case, carburetion system, and fuel tank represent important sources of hydrocarbons for the urban atmosphere. The wear of tires, brake linings, and metal parts contribute to particles being suspended in the air of the near roadside **environment**. The presence of **asbestos** fibers from brake linings in the urban air has often been discussed, although health threats from this source is less serious than from other sources.

There have been relatively few studies of the pollutants inside automobiles, but there has been some concern about the potential hazard of the build-up of automobile emissions from malfunctioning units and from "leaks." These can be from the evaporation of fuel, especially leaded fuels where the volatile tetraethyl lead is present. Carbon monoxide, from the exhaust system, can cause drowsiness and impair judgment. However in many cases the interior of a properly functioning automobile, without additional sources such as smoking, can have somewhat better **air quality** than the air outside. In general, pedestrians, cyclists, and those who work at road sites are likely to experience the worst of automotive pollutants such as carbon monoxide and potentially carcinogenic hydrocarbons.

Although huge quantities of **fossil fuels** are burnt in power generation and a range of industrial processes, automobiles make a significant and growing contribution to **carbon dioxide** emissions which enhance the **greenhouse effect**. **Ethanol**, made from sugar cane, is a renewable source and has the advantage of not making as large a contribution to the **greenhouse gases** as gasoline. Automobiles are not large emitters of **sulfur dioxide** and thus do not contribute greatly to the regional **acid rain** problem. Nevertheless, the **nitrogen oxides** emitted by automobiles are ultimately converted to nitric **acid** and these are making an increasing contribution to rainfall acidity. Diesel-powered vehicles use fuel of a higher sulfur content and can contribute to the sulfur compounds in urban air.

Despite the enormous problems created by the automobile, few propose its abolition. The ownership of a car carries with it powerful statements about personal freedom and power. Beyond this, the structure of many modern cities requires the use of a car. Thus while **air pollution** problems might well be cured by a wide range of sociological changes, a technological fix has been favored, such as the use of catalytic converters. Despite this and other devices, cities still face daunting air quality problems. In some areas, most notably the **Los Angeles Basin**, it is clear that there will have to be a wide range of changes if air quality is to improve. Although much attention is being given to lowering emissions of volatile organic compounds, it is likely that nonpolluting vehicles will have to be manufactured and a better **mass transit** system created.

Autotroph

An organism that derives its **carbon** for building body tissues from **carbon dioxide** (CO_2) or carbonates and obtains its energy for bodily functions from radiant sources, such as sunlight, or from the oxidation of certain inorganic substances. The leaves of green plants and the bacteria that oxidize sulfur, iron, ammonium, and nitrite are examples of

autotrophs. The oxidation of ammonium to nitrite, and of nitrite to nitrate, a process called **nitrification**, is a critical part of the **nitrogen cycle**. Moreover, the creation of food by photosynthetic organisms is largely an autotrophic process.

Avalanche

A sudden slide of snow and ice, usually in mountainous areas where there is heavy snow accumulation on moderate to steep slopes. Snow avalanches flow at an average speed of 80 mph (130 km/hr), and their length can range from less than 300 ft (100 m) to 2 mi (3.2 km) or more. Generally the term "avalanche" refers to sudden slides of snow and ice, but it can also be used to describe catastrophic debris slides consisting of mud and loose rock. Debris avalanches are especially associated with volcanic activity in which melted snow, earthquakes, and clouds of flowing ash can trigger movement of rock and mud. Snow avalanches generally consist either of loose, fresh snow or of slabs of accumulated snow and ice that move in large blocks. Snow avalanches occur most often where the snow surface has melted under the sun and then refreezes, forming a smooth surface of snow. Later snow falling on this smooth surface tends to adhere poorly, and it may slide off the slick plane of recrystallized snow when it is shaken by any form of vibration—including sound waves, earthquakes, or the movement of skiers.

Several factors contribute to snow avalanches, including snow accumulation, hill slope angle, slope shape (profile), and weather. Avalanches are most common where there is heavy snow accumulation on slopes of 25–65°, and they occur most often on slopes between 30° and 45°. On slopes steeper than 65° snow tends to sluff off rather than accumulate. On shallow slopes avalanches are likely to occur only in wet (melting) conditions, when accumulated snow may be heavy, and when snow melt collecting along a hardened old snow surface within the snowpack can loosen upper layers, allowing them to release easily. Slab avalanches may be more likely to start on convex slopes, where snow masses can be fractured into loose blocks, but they rarely begin on tree-covered slopes. However, loose snow avalanches often start among trees, gathering speed and snow as they cross open slopes. Weather can influence avalanche **probability** by changing the **stability** and cohesiveness of the snow pack. Many avalanches occur during storms when snow accumulates rapidly, or during sustained periods of cold weather when new snow remains loose. Like snow melt, rainfall, can increase chances of avalanche by lubricating the surface of hardened layers within the snow pack. Sustained winds increase snow accumulation on the leeward side of slopes, producing snow masses susceptible to slab movement. When conditions are favorable, an avalanche can be triggered by the weight of a person or by loud noises, earthquakes, or other sources of vibration. Avalanches tend to be most common in mid-winter, when snow accumulation is high, and in late spring, when melting causes instability in the snow pack.

Avalanches play an ecological role by keeping slopes clear of trees, thus maintaining openings vegetated by grasses, forbs, and low brush. They are also a geomorphologic force, since they maintain bare rock surfaces, which are susceptible to **erosion**.

Most research into the dynamics and causes of avalanches has occurred in populous mountain regions such as the Alps, the Cascades, and the Rocky Mountains, where avalanches cause damage and fatalities by crushing buildings and vehicles. Avalanches are very powerful: they can crush buildings, remove full-grown trees from hillsides, and even sweep railroad trains from their tracks. One of the greatest avalanche disasters on record occurred in 1910 in the Cascades near Seattle, Washington, when a passenger train, trapped in a narrow valley in a snow storm for several days, was caught in an avalanche and swept to the bottom of the valley. Ninety-six passengers died as the cars were crushed with snow. Although avalanches are among the more dangerous natural hazards, they have caused fewer than 200 recorded mortalities in North America, and most avalanche victims in North America are caught in slides they triggered themselves by walking or skiing across open slopes with accumulated snow.

B

Bacillus thuringiensis

Bacillus thuringiensis, or *B.t.*, is a family of bacterial-based, biological insecticides. Specific strains of *B.t.* are used against a wide variety of leaf-eating lepidopteran pests such as European corn borer, tomato hornworms, and **tobacco** moths, and some other susceptible insects such as blackflies and mosquitoes. The active agent in *B.t.* is toxic organic crystals that bind to the gut of an insect and poke holes in cell membranes, literally draining the life from the insect. *B.t.* can be applied using technology similar to that used for chemical insecticides, such as high-potency, low-volume sprays of *B.t.* spores applied by aircraft. The efficacy of *B.t.* is usually more variable and less effective than that of chemical insecticides, but the environmental effects of *B.t.* are considered to be more acceptable because there is little non-target toxicity.

Background radiation

Ionizing radiation has the potential to kill cells or cause somatic or germinal mutations. It has this ability by virtue of its power to penetrate living cells and produce highly reactive charged ions. It is the charged ions which cause cell damage. Radiation accidents and the potential for radiation from nuclear (atomic) bombs create a fear of radiation release due to human activity. Many people are subjected to diagnostic and therapeutic radiation, and older Americans were exposed to **radioactive fallout** from atmospheric testing of **nuclear weapons**. There is some environmental contamination from nuclear fuel used in **power plants**. Accordingly, there is considerable interest in radiation effects on biological systems and the sources of radiation in the **environment**.

Concern for radiation safety is certainly justified and most individuals seek to minimize their exposure to human-generated radiation. However, for most people, exposure levels to radiation from natural sources far exceed exposure to radiation produced by humans. Current estimates of human exposure levels of ionizing radiation suggest that only about 18% is of human origin. The remaining radiation (82%) is from natural sources and is referred to as "background radiation." While radiation doses vary tremendously from person to person, the average human has an annual exposure to ionizing radiation of about 360 millirem. (Millirem or mrem is a measure of radiation absorbed by tissue multiplied by a factor that takes into account the biological effectiveness of a particular type of radiation and other factors such as the competence of radiation repair. One mrem is equal to 10 μSv; μSv is an abbreviation for microSievert, a unit that is used internationally.)

Some radiation has little biological effect. Visible light and infrared radiation do not cause ionization, are not mutagenic and are not carcinogenic. Consequently, background radiation refers to ionizing radiation which is derived from cosmic radiation, terrestrial radiation, and radiation from sources internal to the body. (Background radiation has the potential for producing inaccurate counts from devices such as a Geiger counter. For example, cosmic rays will be recorded when measuring the **radioactive decay** of a sample. This background "noise" must be subtracted from the indicated count level to give a true indication of activity of the sample.)

Cosmic rays are of galactic origin, entering the earth's **atmosphere** from outer space. Solar activity in the form of sunflares and sunspots affects the intensity of cosmic rays. The atmosphere of the earth serves as a protective layer for humans and anything that damages that protective layer will increase the **radiation exposure** of those who live under it. The dose of cosmic rays doubles at 4,920 ft (1,500 m) above sea level. Because of this, citizens of Denver, near the Rocky Mountains, receive more than twice the dose of radiation from cosmic rays as do citizens of coastal cities such as New Orleans. The **aluminum** shell of a jet airplane provides little protection from cosmic rays, and for this reason passengers and crews of high flying jet airplanes receive more radiation than their earth traveling compatriots. Even greater is the cosmic radiation encountered at 60,000 ft

(18,300 m) where supersonic jets fly. The level of cosmic radiation there is 1,000 times that at sea level. While the cosmic ray dose for occasional flyers is minimal, flight and cabin crews of ordinary jet airliners receive an additional exposure of 160 mrem per year, an added radiation burden to professional flyers of more than 40%. Cosmic sources for non-flying citizens at sea level are responsible for about 8% (29–30 mrem) of background radiation exposure per annum.

Another source of background radiation is terrestrial **radioactivity** from naturally occurring minerals, such as **uranium**, thorium, and cesium, in **soil** and rocks. The abundance of these minerals differs greatly from one geographic area to another. Residents of the Colorado plateau receive approximately double the dose of terrestrial radiation as those who live in Iowa or Minnesota. The geographic variations are attributed to the local composition of the earth's crust and the kinds of rock, soil and minerals present. Houses made of stone are more radioactive than houses made of wood. Limestones and sandstones are low in radioactivity when compared with granites and some shales. Naturally occurring **radionuclides** in soil may become incorporated into grains and vegetables and thus gain access to the human body. **Radon** is a radioactive gas produced by the disintegration of radium (which is produced from uranium). Radon escapes from the earth's crust and becomes incorporated into all living matter including humans. It is the largest source of inhaled radioactivity and comprises about 55% of total human radiation exposure (both background and human generated). Energy efficient homes, which do not leak air, may have a higher concentration of radon inside than is found in outside air. This is especially true of basement air. The radon in the home decays into radioactive "daughters" that become attached to **aerosol** particles which, when inhaled, lodge on lung and tracheal surfaces. Obviously, the level of radon in household air varies with construction material and with geographic location. Is radon in household air a hazard? Many people believe it is, since radon exposure (at a much higher level than occurs breathing household air) is responsible for lung **cancer** in non-smoking uranium miners.

Naturally occurring radioactive **carbon** (carbon-14) similarly becomes incorporated into all living material. Thus, external radiation from terrestrial sources often becomes internalized via food, water, and air. Radioactive atoms (radionuclides) of carbon, uranium, thorium, and actinium and radon gas provide much of the terrestrial background radiation. The combined annual exposure to terrestrial sources, including internal radiation and radon, is about 266 mrem and far exceeds other, more feared sources of radiation.

Life on earth evolved in the presence of ionizing radiation. It seems reasonable to assume that mutations can be attributed to this chronic, low level of radiation. Mutations are usually considered to be detrimental, but over the long course of human and other organic **evolution**, many useful mutations occurred, and it is these mutations that have contributed to the evolution of higher forms.

Nevertheless, it is to an organism's advantage to resist the deleterious effects associated with most mutations. The forms of life that inhabit the earth today are descendants of organisms that existed for millions of years on earth. Inasmuch as background ionizing radiation has been on earth longer than life, humans and all other organisms obviously cope with chronic low levels of radiation. Survival of a particular **species** is not due to a lack of genetic damage by background radiation. Rather, organisms survive because of a high degree of redundancy of cells in the body, which enables organ function even after the death of many cells (e.g., kidney and liver function, essential for life, does not fail with the loss of many cells; this statement is true for essentially all organs of the human body). Further, stem cells in many organs replace dead and discarded cells. Naturally occurring antioxidants are thought to protect against free radicals produced by ionizing radiation. Finally, repair mechanisms exist which can, in some cases, identify damage to the double helix and effect DNA repair. Hence, while organisms are vulnerable to background radiation, mechanisms are present which assure survival.

Sir Francis Bacon (1561 – 1626)

English statesman, author, and philosopher

Sir Francis Bacon, philosopher and Lord Chancellor of England, was one of the key thinkers involved in the development of the procedures and epistemological standards of modern science. Bacon thus has also played a vital role in shaping modern attitudes towards **nature**, human progress, and the **environment**. He inspired many of the great thinkers of the Enlightenment, especially in England and France. Moreover, Bacon laid the intellectual groundwork for the mechanistic view of the universe characteristic of eighteenth and nineteenth century thought and for the explosion of technology in the same period.

Sir Francis Bacon. (Painting by Paul Somer. Corbis-Bettmann. Reproduced by permission.)

In *The Advancement of Learning* (1605) and *Novum Organum* (1620), Bacon attacked all teleological ways of looking at nature and natural processes (i.e., the idea found in Aristotle and in medieval scholasticism that there is an end or purpose which somehow guides or shapes such processes). For Bacon, this way of looking at nature resulted from the tendency of human beings to make themselves the measure of the outer world, and thus to read purely human ends and purposes into physical and biological phenomena. Science, he insisted, must guard against such prejudices and preconceptions if it was to arrive at valid knowledge.

Instead of relying on or assuming imaginary causes, science should proceed empirically and inductively, continuously accumulating and analyzing data through observation and experiment. Empirical observation and the close scrutiny of natural phenomena allow the scientist to make inferences, which can be expressed in the form of hypotheses. Such hypotheses can then be tested through continued observation and experiment, the results of which can generate still more hypotheses. Advancing in this manner, Bacon proposed that science would come to more and more general statements about the laws which govern nature and, eventually, to the secret nature and inner essence of the phenomena it studied.

As Bacon rather famously argued, "Knowledge is power." By knowing the laws of nature and the inner essence of the phenomena studied, human beings can remake things as they desire. All knowledge is for use, and the underlying motivation of science is technical control of nature. Bacon believed that science would ultimately progress to the point that the world itself would be, in effect, merely the raw material for whatever future ideal society human beings decided to create for themselves.

The possible features of this future world are sketched out in Bacon's unfinished utopia, *The New Atlantis* (1627). Here Bacon developed the view that the troubles of his time could be solved through the construction of a community governed by natural scientists and the notion that science and technology indeed could somehow redeem mankind. Empirical science would unlock the secrets of nature thus providing for technological advancement. With technological development would come material abundance and, implicitly, moral and political progress.

Bacon's utopia is ruled by a "Solomon's House"—a academy of scientists with virtually absolute power to decide which inventions, institutions, laws, practices, and so forth will be propitious for society. Society itself is dedicated to advancing the human mastery of nature: "The End of Our Foundation is the Knowledge of Causes and secret motions of things; and the enlarging of the bounds of the human empire, to the effecting of all things possible."

BACT

see **Best available control technology**

Baghouse

An **air pollution control** device normally using a collection of long, cylindrical, fabric **filters** to remove **particulate** matter from an exhaust air stream. The filter arrangement is normally designed to overcome problems of cleaning and handling large exhaust volumes. In most cases, exhaust gas enters long (usually 33–50 ft [10–15 m]), vertical, cylindrical filters on the inside from the bottom. The bags are sealed at the top. As the exhaust air passes through the fabric filter, particles are separated from the air stream by sticking either to the filter fabric or to the cake of particles previously collected on the inside of the filter. The exhaust then passes

Baghouse. (McGraw-Hill Inc. Reproduced by permission.)

to the **atmosphere** free of most of its original particulate-matter **loading**; collection efficiency usually increases with particle size.

The buildup of particles on the inside of the bags is removed periodically by various methods, such as rapping the bags, pulsing the air flow through the bags, or shaking. The particles fall down the long cylindrical bags and are normally caught in a collection bin, which is unloaded periodically. A baghouse system is usually much cheaper to install and operate than a system using **electrostatic precipitation** to remove particulates.

Balance of nature

The ideal of a balance of **nature** is based on a view of the natural world that is largely an artifact created by the temporal, spatial, and cultural **filters** through which humans respond to the natural world. For a variety of reasons we have interpreted the natural course of events in the world around us to maintain equilibrium, and seek to return it to equilibrium when disturbed.

There are three components to nature's balance: ecological, evolutionary, and population. In an ecological sense, communities were thought to proceed through successional stages to a steady state climax. When disturbed, the community would return to that climax state. **Stability** was an endpoint, and once reached the community became a partly closed homeostatic system. In an evolutionary sense, the current compliment of **species** is interpreted as the ultimate product of **evolution**, rather than a temporary expression of a continually changing global taxa. In the population sense, concepts like **carrying capacity** and the constant interplay between environmental **resistance** and biotic potential is interpreted as creating a balance of numbers in a population, and between the population and its **environment**. Three ideas are fundamental to the above; that nature undisturbed is constant, when disturbed nature returns to the constant condition, and constancy in nature is the desired endpoint.

This interpretation of nature may be so strongly filtered by our cultural interpretation and idealization of balance, that we tend to produce conclusions not in keeping with our observations of nature. Assumptions of human centrality may be sufficiently strong to bend the usually clear lens supplied by science in this case. Although the theme of balance in nature has been formally criticized in **ecology** for over 65 years (since Frederick Clements and Henry Gleason focused the argument in the 1920s) the core of the science did not change until about 25 years ago. Since that time, a dynamic approach that pays no special attention to equilibrium processes has taken center stage in ecological theorizing.

The primary alternatives are part of the group of ideas termed intermediate disturbance hypotheses. These ideas offer a different view of how communities assemble, suggesting that disturbance is more frequent and/or more influential than performing a routine return to an equilibrium state. Furthermore, disturbance and non-equilibrium situations are responsible for the most diverse communities, tropical rain forests and coral reefs, through the reduction in **competition** caused by disturbance factors.

Few theorists, however, suggest that non-equilibrium settings are the single most powerful explanation, or are mutually exclusive with communities that do have an equilibrium. There are situations that seem to seek equilibrium, and smaller subsystems that appear virtually closed. In local situations, certain levels of resources and disturbance may create long term stability and **niche** differentiation or other mechanisms may be the principal cause of a species diverse situation.

Although theorists have been working to verify, revise, and examine new developments in ecology, very little attention has been given to alternative, more complex theoretical interpretations of nature, in terms of time, space, and dynamism in resource and environmental management. The im-

plications of accepting a non-equilibrium orientation for environmental management are significant. Most of the underpinnings of resource management include steady state carrying capacity, **succession**, predator-prey balance, and community equilibrium as foundations.

There are three major implications of the shift from equilibrium to non-equilibrium approaches to the environment. First, until a more realistic theory is used, the rate of resource extraction from nature will be subject to considerably higher uncertainty than we currently suspect. Since we expect communities to seek equilibrium, we believe we can predict populations and species numbers to a greater degree than may be warranted. Second, we perceive that areas of high **biodiversity** are due to long and short term stability, when in fact the forces may be just the opposite. Therefore, management that attempts to maintain stability is the reverse of what is actually needed. Third, the kinds of disturbance we create in these diverse communities (**deforestation**, introduction of non-native species, or oil **pollution**) may not mimic anything natural and a species may have little defense against them. A characteristic of communities with high species diversity is small population size, thus human disturbance may cause exceptionally high rates of **extinction**. A central facet of the burgeoning practice of ecological restoration should be an ability to accurately mimic disturbance regimes.

Balance in nature has a strong appeal to our sensibilities and has anchored natural resource management practices. Now practice stands well behind theoretical developments and increased integration of more modern ecological science is required to avoid costly resource management mistakes.

Bald eagle

The bald eagle (*Haliaeetus leucocephalus*), one of North America's largest birds of prey with a wingspan of up to 7.5 ft (2.3 m), is a member of the family Accipitridae. Adult bald eagles are dark brown to black with a white head and tail; immature birds are dark brown with mottled white wings and are often mistaken for golden eagles (*Aquila chrysaetos*). Bald eagles feed primarily on fish, but also eat rodents, other small mammals and carrion. The bald eagle is the national emblem for the United States, adopted as such in 1782 because of its fierce, independent appearance. This characterization is unfounded, however, as this **species** is usually rather timid.

Formerly occurring over most of North America, the bald eagle's range—particularly in the lower 48 states—had been drastically reduced by a variety of reasons. One being its exposure to DDT and related pesticides, which are magnified in the **food chain/web**. This led to reproductive problems, in particular, thin-shelled eggs that were crushed during incubation. The banning of DDT use in the United States in 1972 may have been a turning point in the recovery of the bald eagle. Eagle populations also were depleted due to **lead poisoning**. Estimates are that for every bird that hunters shot and carried out with them, they left behind about a half pound of **lead shot**, which affects the **wildlife** in that **ecosystem** long after the hunters are gone. Since 1980, more than 60 bald eagles have died from lead poisoning. Other threats facing their populations include **habitat** loss or destruction, human encroachment, collisions with high power lines, and shooting.

In 1982 the population in the lower 48 states had fallen to less than 1,500 pairs, but by 1988 their numbers had risen to about 2,400 pairs. Due to strict **conservation** laws, the numbers have continued to rise and there are now 6,000 pairs. On July 4, 2000, the bald eagle was removed from the Endangered listing and is now listed as Threatened in the lower 48 states. The bald eagle is not endangered in the state of Alaska, since a large, healthy population of about 35,000 birds exists there. During the annual **salmon** run, up to 4,000 bald eagles congregate along the Chilkat River in Alaska to feed on dead and dying salmon.

Bald eagles, which typically mate for life and build huge platform nests in tall trees or cliff ledges, have been aided by several recovery programs, including the construction of artificial nesting platforms. They will **reuse**, add to, or repair the same nest annually, and some pairs have been known to use the same nest for over 35 years. Because the bald eagle is listed as either endangered or threatened throughout most of the United States, the federal government provides some funding for its conservation and recovery projects. In 1989, the federal government spent $44 million on the conservation of threatened and **endangered species**. Of the 554 species listed, $22 million, half of the total allotment, was spent on the top 12 species on a prioritized

Bald eagle (*Haliaeetus leucocephalus*). (Photograph by Robert J. Huffman. Field Mark Publications. Reproduced by permission.)

list. The bald eagle was at the top of that list and received $3 million of those funds.

Barrier island

An elongated island that lies parallel to, but mostly separate from, a coastline. Barrier islands are composed of sediments, mainly sand, deposited by longshore currents, wind, and wave action. Both marine and terrestrial plants and animals find **habitat** on barrier islands or along their sandy beach shorelines. These islands also protect coastal lagoons from ocean currents and waves, providing a warm, quiet **environment** for **species** that cannot tolerate more violent wind and wave conditions. In recent decades these linear, sandy islands, with easy access from the mainland, have proven a popular playground for vacationers. These visitors now pose a significant threat to breeding birds and other coastal species. Building houses, roads, and other disruptive human activities can destabilize **dunes** and expose barrier islands to disastrous storm damage. In some cases, whole islands are swept away, exposing protected lagoons and delicate **wetlands** to further damage. Major barrier island formations in North America include those along the eastern coasts of the mid-Atlantic states, Florida, and the Gulf of Mexico.

Located parallel to coastlines, Barrier islands attract visitors that now pose a significant threat to the birds and other coastal species living there. (JLM Visuals. Reproduced by permission.)

Basel Convention

The Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal is a global treaty that was adopted in 1989 and became effective on May 5, 1992. The Basel Convention represents a response by the international community to problems caused by the international shipment of wastes. Of the over 400 million tons of hazardous wastes generated globally every year, an unknown amount is subject to transboundary movement. (United States companies were estimated to export about 140,000 tons of **hazardous waste** in 1993). In the 1980s, several highly publicized "toxic ships" were accused of trying to dump hazardous wastes illegally in developing countries. The uncontrolled movement and disposal of hazardous waste, especially in developing countries which often lacked the know-how and equipment to safely manage and treat hazardous wastes, became a significant problem due to high domestic costs of treating or disposing of wastes.

Through its Secretariat in the **United Nations Environment Programme**, the Convention aims to control the transboundary movement of wastes, monitor and prevent illegal traffic, provide technical assistance and guidelines, and promote cooperation. The Convention imposes obligations on treaty signatories to ensure that wastes are managed and disposed of in an environmentally sound manner. The main principles of the Basel Convention are to (1) reduce transboundary movements of hazardous wastes to a minimum consistent with environmentally sound management; (2) treat and dispose of hazardous wastes as close as possible to their source of generation; and (3) reduce and minimize the generation of hazardous waste. The Convention generally prohibits Parties to the Convention from importing or exporting hazardous wastes or other wastes from or to a non-contracting party. However, a Party to the convention may allow such import or export if the Party has a separate bilateral or multilateral agreement regarding the transboundary movement of hazardous wastes with a non-party and that agreement provides for "environmentally sound management." To date, the Convention has defined environmentally sound management practices for a number of wastes and technologies, including organic solvents, waste oils, pen-

tachloraphenol (PCBs), household wastes, landfills, incinerators, and oil **recycling**.

The Conference of the Parties (COP) is the governing body of the Basel Convention and is composed of all governments that have ratified or acceded to it. The COP has met three times since the Convention entered into force in May 1992 (in Piriapolis, Uruguay, on December 4, 1992; Geneva, Switzerland, on March 25, 1994; and Geneva, Switzerland, September 18–22, 1995). In the most recent meeting, the Parties adopted an amendment to the Convention that will ban the export of hazardous wastes from developed countries to developing ones. The Fourth Meeting of the Conference of the Parties, held in Kuala Lumpur in October 1997, incorporated work on lists of wastes into the system of the Basel Convention. These lists should help to mitigate practical difficulties in determining exactly what is a waste, a problem that has been encountered by a number of Parties.

Currently, the European Community and 108 States are Party to the Basel Convention. Though the United States was among the original signatories to the Basel Convention in 1989, the United States is still not a party to the Convention since Congress has yet to pass implementing legislation. The United States does participate in planning and technical aspects of the Convention.

[*Stuart Batterman*]

Rick Bass. (Photograph by L. L. Griffin. Reproduced by permission.)

Rick Bass (1958 –)

American writer

Bass was born in south Texas and grew up there, absorbing stories and family lore from his grandfather during deer-hunting trips. These early forays into Texas hill country form the basis of the author's first book, *The Deer Pasture*, published when he was 27 years old. At one time or another, Bass has lived in Texas, Mississippi, Vermont, Utah, Arkansas, and Montana.

Bass received a degree in geology from Utah State University in 1979 and went to work as a **petroleum** geologist in Mississippi, prospecting for new oil **wells**. This experience informed one of his better-known nonfiction books, *Oil Notes*. Written in journal form, *Oil Notes* offers meditations on the art and science of finding energy in the ground, as well as reflections on the author's personal life and his outdoor adventures.

Bass is a passionate environmentalist whose nonfiction in particular celebrates efforts to reclaim a wilder America. Books such as *The Lost Grizzlies: A Search for Survivors* demonstrate his conviction that America's larger predators should be allowed to survive and thrive. Bass highlights the plight of the wolf in 1992's *The Ninemile Wolves* and 1998's *The New Wolves*.

Bass features his adopted Montana homeland in some of his publications, including his nonfiction titles *Winter: Notes from Montana*, a 1991 release, and *The Book of Yaak*, which was published in 1996. Bass's essays are often linked by comments about his dog, a German shorthaired pointer named Colter. Bass gave readers a more exclusive look at Colter with his 2000 book *Colter: The True Story of the Best Dog I Ever Had*. The work, however, also stays true to Bass's characteristic nature themes. *Publisher's Weekly* said *Colter* was as much "a book about appreciating nature and life" as it was the story of Bass and his dog.

Although most of Bass's publications are nonfiction, the author has written both short stories and novels. Perhaps not surprisingly, the masculine sports of **hunting**, fishing, and drinking are central to many of Bass's stories. Bass published his first novel in 1998, *Where the Sea Used to Be*. The story involves a young geologist named Wallis who is sent by an oilman named Old Dudley to an isolated part of Montana. While investigating the land, Wallis stays with Mel, Old Dudley's daughter. Wallis comes to love both Mel, who studies **wolves**, and the remote landscape. This book was followed by a collection of short stories in 2002, called *The Hermit's Story*. Bass continued to publish essays and

stories in the early 2000s in many popular magazines, including *Sports Afield*, *Audobon*, *National Geographic Traveler*, *Atlantic Monthly*, *Sierra*, and others.

Bats

Bats, the only mammals that fly, are among nature's least understood and unfairly maligned creatures. They are extremely valuable animals, responsible for consuming huge numbers of insects and pollinating and dispersing the seeds of fruit-bearing plants and trees, especially in the tropics. Yet, superstitions about and fear of these nocturnal creatures have led to their persecution and elimination from many areas, and several **species** of bats are now threatened with **extinction**.

There are over 900 species of bats, representing almost a quarter of all mammal species, and they are found on every continent except **Antarctica**. Most types of bats live in the tropics, and some 40 species are found in the United States and Canada. The largest bats, flying foxes, found on Pacific islands, have wingspreads of five feet (1.5 m). The smallest bats, bamboo bats, are the size of the end of a person's thumb.

Bats commonly feed on mosquitoes and other night-flying insects, especially over ponds and other bodies of water. Some bats consume half of their weight in insects a night, eating up to 5,000 gnat-sized mosquitoes an hour, thus helping to keep insect population under control. Some bats hunt ground-dwelling species, such as spiders, scorpions, large insects, and beetles, and others prey on **frogs**, lizards, small birds, rodents, fish, and even other bats. The infamous vampire bat of Central and South America does actually feed on blood, daily consuming about a tablespoon from cattle and other animals, but it does not generally bother humans.

Bats that live in tropical areas, such as fruit bats (also called flying foxes), often feed on and pollinate plants. Bats are thus extremely important in helping flowers and fruit-bearing plants to reproduce. In tropical rain forests, for example, bats are responsible for pollinating most of the fruit trees and plants.

Bats are usually social animals. Some colonies consist of millions of bats and use the same roost for centuries. Bat manure (**guano**) is often collected from caves and used as **fertilizer**. Most bats come out only at night and spend their days in dark roosts, hanging upside down, sleeping, nursing and tending their young, or grooming their wings and fur. Bats become active an hour or so before dark, and at dusk they leave their roosting areas and fly out to feed, returning home before dawn. Many bats flying at night navigate and locate food, such as flying insects, by echolocation, emitting continuous high frequency sounds that echo or bounce off of nearby objects. Such sounds cannot be heard by humans. Most bats have just one or two young a year, though some have up to four offspring at a time. The newborn must hold onto its mother, sometimes for several weeks, and be nursed for six to eight weeks. Some species of bats live up to 25 years. Most bats in North America migrate or hibernate in caves during the winter, when food is scarce and temperatures reach freezing point. Superstitions about and prejudice against bats have existed for hundreds of years, but most such tales are untrue. Bats do not carry bedbugs or become entangled in women's hair; they are not blind and indeed do not even have poor vision. In fact, except for the occasional rabid bat, these creatures are not dangerous to humans and are quite timid and will try to escape if confronted. In recent years, public education programs and conservationists, such as Dr. Merlin Tuttle, head of Bat Conservation International in Austin, Texas, have helped correct these misconceptions about bats and have increased appreciation for the valuable role these creatures play in destroying pests and pollinating crops. Bracken Cave, located between San Antonio and Austin, is owned by Bat Conservation International and with some 20 million Mexican freetailed bats residing there in the spring and summer, the cave is said to shelter the world's largest bat colony and the largest collection of mammals anywhere on the planet. The pregnant females migrate there in early March from central Mexico to nurse and raise their young, and the colony can consume 250 tons of insects a night.

According to Dr. Tuttle, a colony of just 150 big brown bats can eat almost 40,000 cucumber beetles in a summer, which "means that they've protected local farmers from 18 million root worms, which cost American farmers $1 billion a year," including crop damage and **pesticide** costs. Dr. Tuttle and his organization suggest that people attract the creatures and help provide **habitat** for them by constructing or buying bathouses, which his groups sell. Nevertheless, bats continue to be feared and exterminated throughout the world. Major threats to the survival of bats include intentional killing, loss of habitat (such as old trees, caves, and mines), eviction from barns, attics, and house eaves, pesticide **poisoning**, and vandalism and disturbance of caves where they roost. According to Dr. Tuttle, "Bats are among the most endangered animals in America. Nearly 40 percent of America's 43 species are either endangered or candidates for the list."

Indiana bat (*Myotis sodalis*). (Photograph by Merlin D. Tuttle. Bat Conservation International. Reproduced by permission.)

Over a dozen species of bats worldwide are listed by the **U.S. Department of the Interior** as **endangered species**, including the gray bat (*Myotis grisescens*) of central and southeastern United States; the Hawaiian hoary bat (*Lasiurus cinereus semotus*); the Indiana bat (*Myotis sodalis*) of the eastern and mid-western United States; the Ozark big-eared bat (*Plecotus townsendii ingens*) found in Missouri, Oklahoma, and Arkansas; the Mexican long-nosed bat (*Leptonycteris nivalis*) of New Mexico, Texas, Mexico, and Central America; Sanborn's long-nosed bat (*Leptonycteris sanborni*) of Arizona, New Mexico, Mexico, and Central America; and the Virginia big-eared bat (*Plecotus townsendii virginianus*) found in Kentucky, North Carolina, West Virginia, and Virginia.

Batteries

see **Lead**

Battery recycling

The United States consumes over $10.4 billion in batteries annually, powering everything from children's toys to hearing aids. Because batteries contain certain toxic substances, such as **cadmium**, **lead**, and sulfuric **acid**, introducing them into landfills and other **solid waste** disposal facilities once they are used can be harmful to the **environment** and to public health.

Virtually every type of battery currently in common use—alkaline, lead acid, nickel-cadmium, lithium **ion**, and more—can be recycled to some extent. Even rechargeable batteries, which were designed in part to cut down on the expense and environmental impact of battery consumption, can be recycled after they have lost the ability to hold a charge.

The Universal Waste Rule, an amendment to the **Resource Conservation and Recovery Act** (RCRA) was introduced by the United States **Environmental Protection Agency** (EPA) in 1995 in an effort to lower some of the administrative and financial barriers to collection and **recycling** of batteries and other potentially hazardous household products. It was hoped that making recycling of lead batteries easier and more profitable to recycle would lead to more extensive recycling programs. The rule streamlined the regulatory process for businesses and excluded rechargeable batteries from **hazardous waste** handling requirements. However, individual states had the final determination over whether or not to adopt the amendment.

Further EPA legislation passed in 1996 entitled the Mercury-Containing Rechargeable Battery Management Act (or Battery Act) promotes recycling of rechargeable batteries through a national uniform code that removes obstacles presented by conflicting state recycling laws and regulations. The Battery Act also mandates that manufacturers of portable rechargeable batteries and products use universal recycling labeling, make batteries easy to remove from products, and prohibit the intentional introduction of **mercury**

into batteries (i.e., mercury added beyond the trace amount present naturally).

Some battery manufacturers have created take-back programs, sometimes referred to as product stewardship or extended producer responsibility, to encourage recycling of their products. Manufacturers "take back" used batteries that are returned by consumers, retailers, and community recycling programs. These programs are voluntary in the United States, and are popular in the **European Union** (EU) where they are legally required in many countries. Austria and Germany, for example, require all battery manufacturers to take back batteries at no cost to the consumer.

According to the EPA, over 350 million rechargeable batteries are sold each year in the United States. The industry trade magazine *Electronics Business News* puts worldwide sales of rechargeable batteries at approximately $5.5 billion in 2001. Yet only a small portion of these rechargeable batteries enter the recycling stream, and the batteries have become a significant source of heavy metal contamination at solid waste facilities.

Passage of the Battery Act paved the way for the largest North American take-back battery recycling program, administered by the non-profit Rechargeable Battery Recycling Corporation (RBRC). The RBRC facilitates and promotes awareness of rechargeable battery recycling throughout the United States and Canada. Its activities are funded through licensing fees paid by the by manufacturers of portable rechargeable batteries and products. The RBRC recycles **nickel** cadmium (Ni-Cd), nickel metal hydride (Ni-MH), lithium ion (Li-ion), and small sealed lead (Pb; SSLA) batteries used in cordless phones, power tools, laptop and notebook computers, cell phones, and other portable devices.

Lead-acid batteries, the type of wet-cell battery used in cars, boats, and other vehicles, are one of the most highly recycled products in America. In 1999, 93.3% of lead-acid batteries were recycled, compared to 42% of all paper and 52% of **aluminum** cans. As of early 2002, 42 states had adopted legislation requiring the recycling of lead-acid batteries. Some states charge a deposit fee to consumers who purchase a new lead-acid battery without trading in an old one for recycling. Most states that charge this fee (including Arizona, Minnesota, and New York) refund it if the consumer brings back a used battery for recycling after the purchase. In addition to keeping lead and sulfuric acid out of solid waste facilities, lead-acid battery recycling is a substantial source of recycled polypropylene and generates 2 billion lb (907 million kg) of lead for **reuse** annually.

Most alkaline and carbon-zinc batteries manufactured in the United States since 1993 do not contain added mercury, and therefore are not considered hazardous waste. Because of the perceived reduced risk of these "zero added mercury" batteries to the environment, many communities advise residents to deposit them into their regular trash, where they end up in landfills. This method is sometimes deemed more cost-effective than sorting and transporting these batteries for recycling. However, recycling programs for alkaline batteries are available and growing in popularity.

Bay of Fundy

The Bay of Fundy is a marine **ecosystem** that lies on the northeastern coast of North America, bordering parts of the Canadian provinces of New Brunswick and Nova Scotia and the U.S. state of Maine. It encompasses about 62.5-thousand mi^2 (180-thousand km^2) of marine coastal-shelf **habitat**, mostly less than about 660 ft (200 m) deep. The Bay is renowned for its exceptionally high tides, which can exceed 53 ft (16 m) in its upper reaches in the Minas Basin. These are higher tides than occur anywhere else in the world. During the peak tidal **flooding** of the Bay the flow of water is about 880-million ft^3/s (25-million m^3/s), equivalent to about 2000 times the average flow of the Saint Lawrence River.

The astonishing tides of the Bay of Fundy occur because its long shape, great size, and increasing up-bay shallowness result in its tidal waters "piling up" to great depths. This effect is amplified by the natural period of tidal oscillation of the Bay of about 13 hours, which further pushes against the natural tidal cycle of 12.4 hours. This rare physical phenomenon is known as a "near-resonant response." The tidal heights are particularly extreme in the upper reaches of the Bay, but even in its lower areas small boats are commonly left high and dry during the twice-daily low tides, and rivers may have a reversing tidal bore (or advancing wave)

The Bay of Fundy with the New Brunswick skyline at its shores. (Communications NB. Reproduced by permission.)

moving upstream with each tide. The "Reversing Falls" near the mouth of the Saint John River is another natural phenomenon associated with the great tides of the Bay of Fundy.

The huge tidal flows of the Bay of Fundy result in great **upwellings** of nutrient-rich bottom waters at some places, allowing high rates of **ecological productivity** to occur. The high productivity of marine **phytoplankton** supports a dense **biomass** of small crustaceans known as **zooplankton**, which are fed upon by great schools of small fishes such as herring. The zooplankton and fishes attract large numbers of such seabirds as gulls, phalaropes, and shearwaters to the Bay during the summer and autumn months, and also abundant fin **whales**, humpback whales, northern right whales (this is the most **endangered species** of large whale), harbor porpoises, and white-sided **dolphins**.

The high productivity of the Bay once also supported large stocks of commercial marine **species**, such as cod, haddock, scallop, and others. Unfortunately, most of these potentially renewable resources have been decimated by overfishing. The Bay still, however, supports large commercial fisheries of lobster and herring. There has also been a huge development of **aquaculture** in the lower Bay, especially in the Passamaquoddy Bay area of New Brunswick. In the late 1990s the production of Atlantic **salmon** had a value exceeding $100-million (Canadian). The intense management systems associated with salmon aquaculture have caused environmental damages in the vicinity of the holding pens, including the build-up of **organic waste**, contamination with anti-fouling **chemicals** and antibiotics, and genetic "pollution" caused when escaped fish inter-breed with the endangered native salmon of the Bay.

In shallow areas, the extreme tidal ranges of the Bay expose extensive mudflats at low tide. In some parts of the upper Bay these mudflats are utilized by immense numbers of shorebirds during their autumn **migration**. The most abundant of these is the semi-palmated sandpiper, one of the most abundant shorebirds in the world. During its autumn migration, hundreds of thousands of these birds feed on mud shrimp in exposed mudflats at low tide, and then aggregate in dense numbers on shingle beaches at high tide. The sandpipers greatly increase their body weight during the several weeks they spend in the upper Bay of Fundy, and then leave for a non-stop flight to South America, fuelled by the fat laid down in the Bay.

During the early 1970s there was a proposal to develop a huge tidal-power facility at the upper Bay of Fundy, to harvest commercial energy from the immense, twice-daily flows of water. The tidal barrage would have extended across the mouth of Minas Basin, a relatively discrete embayment with a gigantic tidal flow. Partly because of controversy associated with the enormous environmental damages that likely would have been caused by this ambitious development, along with the extraordinary construction costs and untried technology, this tidal-power facility was never built. A much smaller, demonstration project of 20 MW was commissioned in 1984 at Annapolis Royal in the upper Bay, and even this facility has caused significant local damages.

Beach renourishment

Beach renourishment, also called beach recovery or replenishment, is the act of rebuilding eroded beaches with offshore sand and gravel that is dredged from the sea floor. Renourishment projects are sometimes implemented to widen a beach for more recreational capacity, or to save structures built on an eroding sandy shoreline. The process is one that requires ongoing maintenance; the shoreline created by a renourished beach will eventually erode again. According to the **National Oceanic and Atmospheric Administration** (NOAA), the estimated cost of long-term restoration of a beach is between $3.3 and $17.5 million per mile.

The process itself involves **dredging** sand from an offshore site and pumping it onto the beach. The sand "borrow" or dredging site must also be carefully selected to minimize any negative environmental impact. Dredging can stir up **silt** and bottom **sediment** and cut off oxygen and light to marine **flora** and **fauna**.

Under the Energy and Water Development Appropriations Act of 2002, 65% of beach renourishment costs are paid for with federal funds, and the remaining 35% with state and local monies. Beach renourishment programs are often part of a state's coastal zone management program. In some cases, state and local government work with the U.S. Army Corp of Engineers to evaluate and implement an **erosion** control program such as beach renourishment.

Environmentalists argue that renourishment is for the benefit of commercial and private development, not for the benefit of the beach. Erosion is a natural process governed by weather and sea changes, and critics charge that tampering with it can permanently alter the **ecosystem** of the area in addition to threatening endangered sea turtle and seabird nesting habitats.

In some cases, it is the coastal development that brings about the need for costly renourishment projects. Coastal development can hasten the erosion of beaches, displacing **dunes** and disrupting beach grasses and other natural barriers. Other human constructions, such as sea walls and other armoring, can also alter the shoreline.

Results of a U.S. **Army Corps of Engineers** Study completed in 2001—the Biological Monitoring Program for Beach Nourishment Operations in Northern New Jersey (Manasquan Inlet to Asbury Park Section)—found that although dredging in the borrow area had a negative impact on local marine life, most **species** had fully recovered within 24–30 months. Further studies are needed to determine the full long-range impact of beach renourishment programs on **biodiversity** and local coastal habitats.

Mollie Beattie (1947 – 1996)

American forester and conservationist

Mollie Hanna Beattie was trained as a forester, worked as a land manager and administrator, and ended her brief career as the first woman to serve as director of the U.S. **Fish and Wildlife Service**. Beattie's bachelor's degree was in

philosophy, followed by a master's degree in forestry from the University of Vermont in 1979. Later (in 1991), she used a Bullard Fellowship at Harvard University to add a master's degree in public administration.

Early in her career, Mollie Beattie served in several **conservation** administrative posts and land management positions at the state level. She was commissioner of the Vermont Department of Forests, Parks, and **Recreation** (1985–1989), and deputy secretary of the state's Agency of **Natural Resources** (1989–1990). She also worked for private foundations and institutes: as program director and lands manager (1983–1985), for the Windham Foundation, a private, nonprofit organization concerned with critical issues facing Vermont, and later (1990–1993), as executive director of the Richard A. Snelling Center for Government in Vermont, a public policy institute.

Before becoming director of the Fish and **Wildlife** Service, Beattie was perhaps most widely known (especially in New England) for the book she co-authored on managing woodlots in private ownership, an influential guide reissued in a second edition in 1993. As a reviewer noted about the first edition, for the decade it was in print "thousands of landowners and professional foresters [recommended the book] to others." Especially noteworthy is the book's emphasis on the responsibility of private landowners for effective stewardship of the land. This background was reflected in her thinking as Fish and Wildlife director by making the private lands program—conservation in partnership with private land-owners—central to the agency's conservation efforts.

As director of the Fish and Wildlife Service, Beattie quickly became nationally known as a strong voice for conservation and as an advocate for thinking about land and **wildlife management** in **ecosystem** terms. One of her first actions as director was to announce that "the Service [will] shift to an ecosystem approach to managing our fish and wildlife resources." She emphasized that people use natural ecosystems for many purposes, and "if we do not take an ecosystem approach to conserving **biodiversity**, none of [those uses] will be long lived."

Her philosophy as a forester, conservationist, administrator, and land manager was summarized in her repeated insistence that people must start making better connections—between wildlife and **habitat** health and human health; between their own actions and "the destiny of the ecosystems on which both humans and wildlife depend;" and between the well-being of the **environment** and the well-being of the economy." She stressed "even if not a single job were created, wildlife must be conserved" and that the diversity of natural systems must remain integral and whole because "we humans are linked to those systems and it is in our immediate self interest to care" about them. She reiterated that in any frame greater than the short-term, the economy and the environment are "identical considerations."

Though Beattie's life was relatively short, and her tenure at the Fish and Wildlife Service cut short by illness, her ideas were well received in conservation circles and her influence continues after her death, helping to create what she called "preemptive conservation," anticipating crises before they appear and using that foresight to minimize conflict, to maintain biodiversity and sustainable economies, and to prevent extinctions.

Bees

see **Africanized bees**

Bellwether species

The term bellwether came from the practice of putting a bell on the leader of a flock of sheep. The term is now used to describe an indicator of a complex of ecological changes. Bellwether **species** are also called indicator species and are seen as early warning signs of environmental damage and **ecosystem** change.

Ecologists have identified many bellwether species in various ecosystems, including the Attwater **prairie** chicken(-*Tympanuchus cupido attwateri*), the Northern diamondback terrapin(*Malaclemys terrapin terrapin*), the Northern and Southern giant petrels (*Macronectes giganteus* and *M. halli*), and the polar bear(*Ursus maritimus*). There are many more. Problems with these species are extreme indicators of troubles within their ecosystems.

The Attwater prairie chicken is almost extinct. It once numbered in the millions in Louisiana and along the Texas

coast. The Northern and Southern giant petrels, large **scavenger** birds of the Antarctic Peninsula, are also heading towards **extinction** as **commercial fishing** fleets head further and further south. In Massachusetts' Outer Cape, conservationists are trying to save the Northern diamondback terrapin. Troubles for the Arctic polar bear are indicating ecosystem change in the Arctic, as humans interact more and more with that ecosystem.

Below Regulatory Concern

Large populations all over the globe continue to be exposed to low-level radiation. Sources include natural **background radiation**, widespread medical uses of **ionizing radiation**, releases and leakages from **nuclear power** and weapons manufacturing plants and waste storage sites. An added potential hazard to public health in the United States stems from government plans to deregulate **low-level radioactive waste** generated in industry, research, and hospitals and allow it to be mixed with general household trash and industrial waste in unprotected dump sites.

The **Nuclear Regulatory Commission** (NRC) plans to deregulate some of this **radioactive waste** and treat it as if it were not radioactive. The makers of radioactive waste have asked the NRC to treat certain low levels of **radiation exposure** with no regulations. The NRC plan, called Below Regulatory Concern (BRC), will categorize some of this waste as acceptable for regular dumping or **recycling**. It will deregulate radioactive consumer products, manufacturing processes and anything else that their computer models project would, on a statistical average, cause radiation exposures within the acceptable range. The policy sets no limits on the cumulative exposure to radiation from multiple sources or exposures or multiple human use.

In July 1991 the NRC responded to public pressure and declared a moratorium on the implementation of BRC policy. This was a temporary move, leaving the policy intact. The U. S. Department of Energy (DoE) has already dumped radioactive trash on unlicensed incinerators. Although DoE is not regulated by the NRC, this action reflects an adoption of the BRC concept. If the BRC plan is eventually approved, radioactive waste will end up in local landfills, sewage systems, incinerators, recycling centers, consumer products and building materials, **hazardous waste** facilities and farmland (through **sludge** spreading).

Some scientists maintain that there are acceptable low levels of radiation exposure (in addition to natural background radiation) that do not pose a threat to public health. Other medical studies conclude that there is no safe level of radiation exposure. Critics claim BRC policy is nothing more than linguistic **detoxification** and will, if implemented, inevitably lead to increased radiation exposure levels to the public, and increased risk of **cancer**, **birth defects**, reduced immunity, and other health problems. Implementation of BRC may also mean that efficient cleanup of contaminated **nuclear weapons** plants (Oak Ridge, Savannah River, Fernald), nuclear reactors, and other radioactive facilities might not be completed.

Its critics contend that BRC is basically a financial, not a public health, decision. The nuclear industry has projected that it will save hundreds of millions of dollars if BRC is implemented.

Hugh Hammond Bennett (1881 – 1960)

American soil conservationist

Dr. Bennett, a noted conservationist, is often called the father of **soil conservation** in the United States. He was born on April 13, 1881, in Anson County, North Carolina, and died July 7, 1960. He is buried in Arlington National Cemetery.

Dr. Bennett graduated from the University of North Carolina in 1903. After completing his university education, he became a **soil** surveyor in the Bureau of Soils of the **U.S. Department of Agriculture**. He recognized early the degradation to the land from soil **erosion** and in 1929 published a bulletin entitled "Soil Erosion, A National Menace." Soon after that, the nation began to heed the admonitions of this young scientist.

In 1933, the U.S. Department of Interior set up a Soil Erosion Service to conduct a nation-wide demonstration program of soil erosion, with Bennett as its head. In 1935,

the **Soil Conservation Service** was established as a permanent agency of the U.S. Department of Agriculture, and Bennett became its head, a position he retained until his retirement in April 1951. He was the author of several books and many technical articles on soil **conservation**. He received high awards from many organizations and several foreign countries.

Dr. Bennett traveled widely as a crusader for soil conservation, and was a forceful speaker. Many colorful stories about his speeches exist. Perhaps the most widely quoted concerns the dust storm that hit Washington D.C. in the spring of 1935 at a critical moment in Congressional hearings concerning legislation that, if passed, would establish the Soil Conservation Service. A huge dust cloud that had started in the Great Plains was steadily moving toward Washington. As the storm hit the district, Dr. Bennett, who had been testifying before members of the Senate public lands committee, called the committee members to a window and pointed to the sky, darkened from the dust. It made such an impression that legislation was promptly approved, establishing the Soil Conservation Service.

Dr. Bennett was an outstanding scientist and crusader, but he was also an able administrator. He visualized that if the Soil Conservation Service was to be effective, it must have grass roots support. He laid the foundation for the establishment of the local soil conservation districts with locally elected officials to guide the program and Soil Conservation Service employees to provide the technical support. Currently there are over 3,000 districts (usually by county). The National Association of Conservation Districts is a powerful voice in matters of conservation. Because of Dr. Bennett's leadership in the United States, soil erosion was increasingly recognized worldwide as a serious threat to the long-term welfare of humans. Many other countries then followed the United States' lead in establishing organized soil conservation programs.

Benzene

A hydrocarbon with chemical formula C_6H_6, benzene contains six **carbon** atoms in a ring structure. A clear volatile liquid with a strong odor, it is one of the most extensively used **hydrocarbons**. Because it is an excellent solvent and a necessary component of many industrial **chemicals**, including **gasoline**, benzene is classified by United States federal agencies as a known human **carcinogen** based on studies that show an increased incidence of nonlymphocytic **leukemia** from occupational exposure and increased incidence of neoplasia in rats and mice exposed by inhalation and gavage. Because of these cancer-causing properties, benzene has been listed as a hazardous air pollutant under Section 112 of the **Clean Air Act**.

Benzo(a)pyrene

Benzo(a)pyrene [B(a)P] is a polycyclic aromatic hydrocarbon (PAH) having five aromatic rings in a fused, honeycomb-like structure. Its formula and molecular weight are $C_{20}H_{12}$ and 252.30, respectively. It is a naturally occurring and man-made organic compound formed along with other PAH in incomplete **combustion** reactions, including the burning of **fossil fuels**, motor vehicle exhaust, wood products, and cigarettes. It is classified as a known human **carcinogen** by the EPA, and is considered to be one of the primary carcinogens in **tobacco smoke**. Synthesized in 1933, it was the first carcinogen isolated from **coal** tar and often serves as a surrogate compound for **modeling** PAHs.

Wendell Erdman Berry (1934 –)

American writer, poet, and conservationist

A Kentucky farmer, poet, novelist, essayist and conservationist, Berry has been a persistent critic of large-scale industrial agriculture—which he believes to be a contradiction in terms—and a champion of environmental stewardship and **sustainable agriculture**. Wendell Erdman Berry was born on August 5, 1934, in Henry County, Kentucky, where his family had farmed for four generations. Although he learned the farmer's skills, he did not wish to make his living as a farmer but as a writer and teacher. He earned his B.A. in English at the University of Kentucky in 1956 and an M.A. in 1957. He was awarded a **Wallace Stegner** writing fellow at Stanford University (1958–1959), where he remained to teach in the English Department (1959–1960). He spent the following year in Italy on a Guggenheim fellowship. In 1962 Berry joined the English faculty at New York University.

Dissatisfied with urban life and feeling disconnected from his roots, in 1965 Berry resigned his professorship of English at New York University to return to his native Kentucky to farm, to write, and to teach at the University of Kentucky. His recurring themes—love of the land, of place or region, and the responsibility to care for them—appear in his poems and novels and in his essays. Many modern farming practices, as he argues in *The Unsettling of America* (1977) and *The Gift of Good Land* (1981) and elsewhere, deplete the **soil**, despoil the **environment**, and deny

the value of careful husbandry. In relying on industrial scales, techniques and technologies, they fail to appreciate that agriculture is agri-culture—that is, a coherent way of life that is concerned with the care and cultivation of the land—rather than agri-business concerned solely with maximizing yields, efficiency, and short-term profits to the long-term detriment of the land, of family farms, and of local communities. A truly sustainable agriculture, as Berry defines it, "would deplete neither soil, nor people, nor communities."

Berry believes that too few people now live on and farm the land, leaving it to the less-than-tender mercies of corporate "managers" who know more about accounting than about agricultural stewardship. The so-called miracle of modern agriculture has been purchased by selling our birthright, the God-given gift of good land that Americans have heedlessly traded for the ease, convenience and affluence of urban and suburban living. As a consequence we have become disconnected from our cultural roots and have lost a **sense of place** and purpose and pleasure in work well done. We have also lost a sense of connection with the land and the lore of those who work on and care for it. Instead of food from our own fields, water from rainfall and **wells**, and stories from family and friends, most Americans now get food from the grocery store, water from the faucet, and endless entertainment from television. A wasteful throwaway society produces not only material but cultural junk—throwaway farms, throwaway marriages and children, disposable communities, and a wanton disregard for the natural environment. The transition to a culture of consumption and convenience, Berry believes, does not represent progress so much as it marks a deep and lasting loss.

Although Berry does not believe it possible (or desirable) that all Americans become farmers, he holds that we need think about what we do daily as consumers and citizens and how our choices and activities affect the land. He suggests that the act of planting and tending a garden is a "complete act" in that it enables one to connect consumption with production, and both to a sense of reverence for the fertility and abundance of a world well cared for.

Best available control technology

Best available control technology (BACT) is a standard used in **air pollution control** in the prevention of significant deterioration (PSD) of **air quality** in the United States. Under the **Clean Air Act**, a major stationary new source of **air pollution**, such as an industrial plant, is required to have a permit that sets **emission** limitations for the facility. As part of the permit, limitations are based on levels achievable by the use of BACT for each pollutant.

To prevent risk to human health and public welfare, each region in the country is placed in one of three PSD areas in compliance with National Ambient Air Quality Standards (NAAQS). Class I areas include national parks and **wilderness** areas, where very little deterioration of air quality is allowed. Class II areas allow moderate increases in ambient concentrations. Those classified as Class III permit industrial development and larger increments of deterioration. Except for national parks, most of the land in the United States is set at Class II.

Under the Clean Air Act, the BACT standards are applicable to all plants built after the effective date, as well as preexisting ones whose modifications might increase emissions of any pollutant. To establish a major new source in any PSD area, an applicant must demonstrate, through monitoring and diffusion models, that emissions will not violate NAAQS or the Clean Air Act. The applicant must also agree to use BACT for all pollutants, whether or not that is necessary to avoid exceeding the levels allowed and despite its cost. The **Environmental Protection Agency** (EPA) requires that a source use the BACT standards, unless it can demonstrate that its use is infeasible based on "substantial and unique local factors." Otherwise BACT, which can include design, equipment, and operational standards, is required for each pollutant emitted above minimal defined levels.

In areas that exceed NAAQS for one or more pollutants, permits are issued only if total allowable emissions of each pollutant are reduced even though a new source is added. The new source must comply with the **lowest achievable emission rate** (LAER), the most stringent limitations possible for a particular plant.

Under the Clean Air Act, if a new stationary source is incapable of BACT standards, it is subject to the **New Source Performance Standard** (NSPS) for a pollutant, as

determined by the EPA. NSPSs take into consideration the cost and energy requirements of emission reduction processes, as well as other health and environmental impacts. This contrasts with BACT standards, which are determined without regard to cost. Strict BACT requirements resulted in a more than 20% reduction in particulates and **sulfur dioxide** below NSPS levels.

Best management practices

Best management practices (BMPs) are methods that have been determined to be the most effective and practical means of preventing or reducing non-point source **pollution** to help achieve **water quality** goals. BMPS include both measures to prevent pollution and measures to mitigate pollution.

BMPS for agriculture focus on reducing non-point sources of pollution from croplands and farm animals. Agricultural **runoff** may contain nutrients, **sediment**, animal wastes, salts, and pesticides. With **conservation tillage**, crop residue, which is plant residue from past harvests, is left on the **soil** surface to reduce runoff and soil **erosion**, conserve soil moisture, and keep nutrients and pesticides on the field. Contour strip farming, where sloping land is farmed across the slopes to impede runoff and soil movement downhill, reduces erosion and sediment production. Managing and accounting for all **nutrient** inputs to a field ensures that there are sufficient nutrients available for crop needs while preventing excessive nutrient **loading**, which may result in **leaching** of the excess nutrients to the ground water. Various BMPs are available for keeping insects, weeds, disease, and other pests below economically harmful levels. **Conservation** buffers, including grassed waterways, **wetlands**, and riparian areas act as an additional barrier of protection by capturing potential pollutants before they move to surface waters. Cows can be kept away from streams by streambank fencing and installation of alternative water sources. Designated stream crossings can provide a controlled crossing or watering access, thus limiting streambank erosion and streambed trampling.

Coastal shorelines can also be protected with BMPs. Shoreline stabilization techniques include headland breaker systems to control shoreline erosion while providing a community beach. Preservation of shorelines can be accomplished through revegetation, where living plant materials are a primary structural component in controlling erosion caused by land instability.

Stormwater management in urban developed areas also utilize BMPs to remove pollutants from runoff. BMPS include retention ponds, alum treatment systems, constructed wetlands, sand **filters**, baffle boxes, inlet devices, vegetated swales, **buffer** strips, and infiltration/exfiltration trenches. A storm drain stenciling programs is an educational BMP tool to remind persons of the illegality of dumping litter, oil, pesticides, and other toxic substances down **urban runoff drainage** systems.

Logging activities can have adverse impacts on stream water temperatures, stream flows, and water quality. BMPS have been developed that address location of logging roads, skid trails, log landings and stream crossings, riparian management buffer zones, management of litter and fuel and lubricant spills, and reforestation activities.

Successful control of erosion and **sedimentation** from construction and mining activities involves a system of BMPs that targets each stage of the erosion process. The first stage involves minimizing the potential sources of sediment by limiting the extent and duration of land disturbance to the minimum needed, and protecting surfaces once they are exposed. The second stage of the BMP system involves controlling the amount of runoff and its ability to carry sediment by diverting incoming flows and impeding internally generated flows. The third stage involves retaining sediment that is picked up on the project site through the use of sediment-capturing devices. **Acid** drainage from mining activities requires even more complex BMPs to prevent acids and associated toxic pollutants from harming surface waters.

Other pollutant sources for which BMPS have been developed include **atmospheric deposition**, boats and marinas, **habitat** degradation, roads, septic systems, underground storage tanks, and **wastewater** treatment.

Best practical technology

Best practical technology (BPT) refers to any of the categories of technology-based **effluent** limitations pursuant to Section 301(b) and Sections 304(b) of the **Clean Water Act** as amended. These categories are the best practicable control technology currently available (BPT); the **best available control technology** (BAT) economically feasible (BAT); and the best **conventional pollutant** control technology (BCT).

Section 301(b) of the Clean Water Act specifies that "in order to carry out the objective of this Act there shall be achieved—(1)(A) not later than July 1, 1977, effluent limitations for point sources, other than publicly owned treatment works (i) which shall require the application of the best practicable control technology currently available as defined by the Administrator pursuant to Section 304(b) of this Act, or (ii) in the case of **discharge** into a publicly owned treatment works which meets the requirements of subparagraph (B) of this paragraph, which shall require compliance with any applicable pretreatment requirements and any requirements under Section 307 of this Act;..."

The BPT identifies the current level of treatment and is the basis of the current level of control for direct discharges. BACT improves on the BPT, and it may include operations or processes not in common use in industry. BCT replaces BACT for the control of conventional pollutants, such as **biochemical oxygen demand** (BOD), total suspended solids (TSS), fecal coliform, and **pH**. Details such as the amount of constituents, and the chemical, physical, and biological characteristics of pollutants, as well as the degree of effluent reduction attainable through the application of the selected technology can be found in the development documents published by the **Environmental Protection Agency** (EPA). These development documents cover different industrial categories such as diary products processing, soap and **detergents** manufacturing, meat products, grain mills, canned and preserved fruits and vegetables processing, and **asbestos** manufacturing.

In accordance with Section 304(b) of the Clean Water Act, the factors to be taken into account in assessing the BPT include the total cost of applying the technology in relation to the effluent reductions to the results achieved from such an application, the age of the equipment and facilities involved, the process employed, the engineering aspects of applying various types of control technologies and process changes, and calculations of environmental impacts other than **water quality** (including energy requirements). As far as evaluating the BCT is concerned, the factors are mostly the same. By they include consideration of the reasonableness of the relationship between the costs of attaining a reduction in effluents and the benefits derived from that reduction, and the comparison of the cost and level of reduction of such pollutants from the discharge from publicly owned treatment works to the cost and level of reduction of such pollutants from a class or category of industrial sources. Control technologies may include in-plant control and preliminary treatment, and end-of-pipe treatment, examples of which are **water conservation** and **reuse**, raw materials substitution, screening, multimedia **filtration**, and activated **carbon absorption**.

[*James W. Patterson*]

Beta particle

An electron emitted by the nucleus of a radioactive atom. The beta particle is produced when a **neutron** within the nucleus decays into a proton and an electron. Beta particles have greater penetrating power than alpha particles but less than x-ray or gamma rays. Although beta particles can penetrate skin, they travel only a short distance in tissue. Beta rays pose relatively little health hazard, therefore, unless they are ingested into the body. Naturally radioactive materials such as potassium-40, carbon-14, and strontium-90 emit beta particles, as do a number of synthetic radioactive materials. *See also* Radioactivity

Beyond Pesticides

Founded in 1981, Beyond Pesticides (originally called the National Coalition Against the Misuse of Pesticides) is a non-profit, grassroots network of groups and individuals concerned with the dangers of pesticides. Members of Beyond Pesticides include individuals, such as "victims" of pesticides, physicians, attorneys, farmers and farmworkers, gardeners, and former chemical company scientists, as well as health, farm, consumer, and church groups. All want to limit **pesticide** use through Beyond Pesticides, which publishes information on pesticide hazards and alternatives, monitors and influences legislation on pesticide issues, and provides seed grants and encouragement to local groups and efforts.

Administrated by a 15-member board of directors and a small full-time staff, including a toxicologist and an ecologist, Beyond Pesticides is now the most prominent organiza-

tion dealing with the pesticide issue. It was established on the premise that much is unknown about the toxic effects of pesticides and the extent of public exposure to them. Because such information is not immediately forthcoming, members of Beyond Pesticides believe the only available way of reducing both known and unknown risks is by limiting or eliminating pesticides. The organization takes a dual-pronged approach to accomplish this. First, Beyond Pesticides draws public attention to the risks of conventional **pest** management; second, it promotes the least-toxic alternatives to current pesticide practices.

An important part of Beyond Pesticides's overall program is the Center for Community Pesticide and Alternatives Information. The Center is a clearinghouse of information, providing a 2,000-volume library about pest control, **chemicals**, and pesticides. To concerned individuals it sells inexpensive brochures and booklets, which cover topics such as alternatives to controlling specific pests and chemicals; the risks of pesticides in schools, to food, and in reproduction; and developments in the **Federal Insecticide, Fungicide and Rodenticide Act** (FIFRA), the national law governing pesticide use and registration in the United States. Through the Center Beyond Pesticides also publishes *Pesticides and You* (*PAY*) five times a year. It is a newsletter sent to approximately 4,500 people, including Beyond Pesticides members, subscribers, and members of Congress. The Center also provides direct assistance to individuals through access to Beyond Pesticides's staff ecologist and toxicologist.

In 1991 Beyond Pesticides also established the Local Environmental Control Project after the Supreme Court decision affirming local communities' rights to regulate pesticide use. Although Beyond Pesticides supported bestowing local control over pesticide use, it needed a new program to counteract the subsequent mobilization of the pesticide industry to reverse the Supreme Court decision. The Local Environmental Control Project campaigns first to preserve the right accorded by the Supreme Court decision and second to encourage communities to take advantage of this right.

Beyond Pesticides marked its tenth anniversary in 1991 with a forum entitled "A Decade of Determination: A Future of Change." It included workshops on **wildlife** and **groundwater** protection, **cancer risk assessment**, and the implications of GATT and free trade agreements. Beyond Pesticides has also established the annual National Pesticide Forum. Through such conferences, its aid to victims and groups, and its many publications, Beyond Pesticides above all encourages local action to limit pesticides and change the methods of controlling pests.

Bhopal, India

On December 3, 1984, one of the world's worst industrial accidents occurred in Bhopal, India. Along with Three Mile Island and Chernobyl, Bhopal stands as an example of the dangers of industrial development without proper attention to **environmental health** and safety.

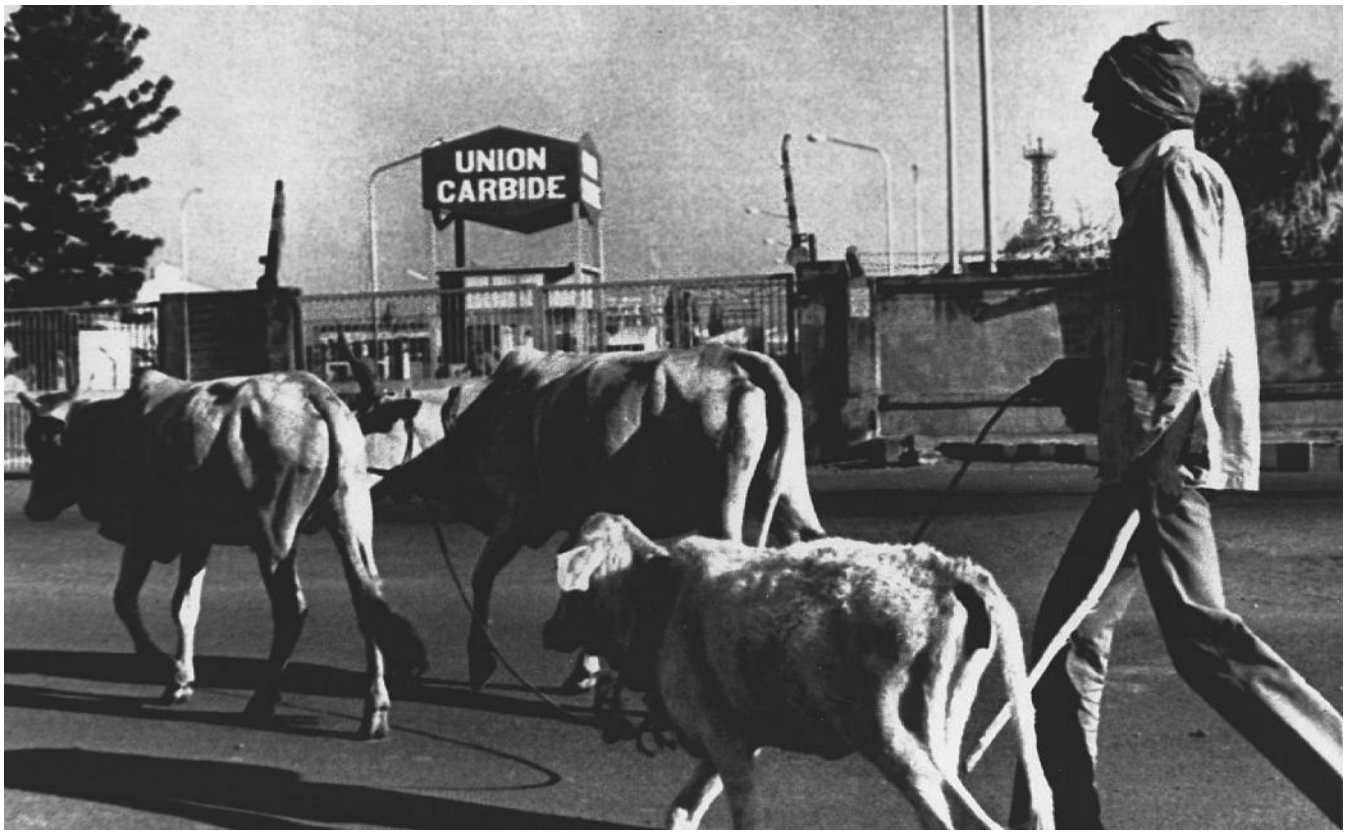
A large industrial and urban center in the state of Madhya Pradesh, Bhopal was the location of a plant owned by the American chemical corporation, Union Carbide, Inc. and its Indian subsidiary, Union Carbide India, Ltd. The plant manufactured pesticides, primarily the **pesticide** carbaryl (marketed under the name Sevin), which is one of the most widely used carbamate class pesticides in the United States and throughout the world. Among the intermediate chemical compounds used together to manufacture Sevin is methyl isocyanate (MIC)—a lethal substance that is reactive, toxic, volatile, and flammable. It was the uncontrolled release of MIC from a storage tank in the Bhopal facility that caused the death of 5,000 people, seriously injured another 20,000 and affected an estimated 200,000 people. The actual number of casualties remains unknown; many believe the numbers cited above to be serious underestimates.

MIC ($CH_3-N=C=O$) is highly volatile and has a boiling point of 89°F (39.1°C). In the presence of trace amounts of impurities such as water or metals, MIC reacts to generate heat, and if the heat is not removed, the chemical begins to boil violently. If relief valves, cooling systems and other safety devices fail to operate in a closed storage tank, the pressure and heat generated may be sufficient to cause a release of MIC into the **atmosphere**. Because the vapor is twice as heavy as air, the vapors if released remain close to the ground where they can do the most damage, drifting along prevailing wind patterns. As set by the Occupational Health and Safety Administration (OSHA), the standards for exposure to MIC are set at 0.02 ppm over an eight-hour period. The immediate effects of exposure, inhalation and ingestion of MIC at high concentrations (above 2 ppm) are burning and tearing of the eyes, coughing, vomiting, blindness, massive trauma of the gastrointestinal tract, clogging of the lungs and suffocation of bronchial tubes. When not immediately fatal, the long-term health consequences include permanent blindness, permanently impaired lung functioning, corneal ulcers, skin damage, and potential **birth defects**.

Many explanations for the disaster have been advanced, but the most widely accepted theory is that trace

amounts of water entered the MIC storage tank and initiated the hydrolysis reaction, which was followed by MIC's spontaneous reactions. The plant was not well designed for safety, and maintenance was especially poor. Four key safety factors should have contained the reaction, but it was later discovered that they were all inoperative at the time of the accident. The refrigerator that should have slowed the reaction by cooling the chemical was shut off, and, as heat and pressure built up in the tank, the relief valve blew. A vent gas scrubber designed to neutralize escaping gas with caustic soda failed to work. Also, the flare tower that would have burned the gas to harmless by-products was under repair. Yet even if all these features had been operational, subsequent investigations found them to be poorly designed and insufficient for the capacity of the plant. Once the runaway reaction started, it was virtually impossible to contain.

The poisonous cloud of MIC released from the plant was carried by the prevailing winds to the south and east of the city—an area populated by highly congested communities of poorer people, many of whom worked as laborers at the Union Carbide plant and other nearby industrial facilities. Released at night, the silent cloud went undetected by residents who remained asleep in their homes, thus possibly ensuring a maximal degree of exposure. Many hundreds died in their sleep, others choked to death on the streets as they ran out in hopes of escaping the lethal cloud. Thousands more died in the following days and weeks. The Indian government and numerous volunteer agencies organized a massive relief effort in the immediate aftermath of the disaster consisting of emergency medical treatment, hospital facilities, and supplies of food and water. Medical treatment was often ineffective, for doctors had an incomplete knowledge of the toxicity of MIC and the appropriate course of action.



In the weeks following the accident, the financial, legal and political consequences of the disaster unfolded. In the United States Union Carbide's stock dipped 25% in the week immediately following the event. Union Carbide India Ltd. (UCIL) came forward and accepted moral responsibility for the accident, arranging some interim financial compensation for victims and their families. However its parent company, Union Carbide Inc., which owned 50.9% of UCIL, refused to accept any legal responsibility for their subsidiary. The Indian government and hundreds of lawyers on both sides pondered issues of liability and the question of a settlement. While Union Carbide hoped for out-of-court settlements or lawsuits in the Indian courts, the Indian government ultimately decided to pursue class action suits on behalf of the victims in the United States courts in the hope of larger settlements. The United States courts refused to hear the case, and it was transferred to the Indian court system. Warren Anderson, then chairman of Union Carbide, refused to appear in Indian court. The case is still under litigation and the interim compensation set aside has reached only a fraction of the victims.

The disaster in Bhopal has had far-reaching political consequences in the United States. A number of Congressional hearings were called and the **Environmental Protection Agency** (EPA) and OSHA initiated inspections and investigations. A Union Carbide plant in McLean, Virginia, that uses processes and products similar to those in Bhopal was repeatedly inspected by officials. While no glaring deficiencies in operation or maintenance were found, it was noted that several small leaks and spills had occurred at the plant in previous years that had gone unreported. These added weight to growing national concern about workers' **right-to-know** provisions and emergency response capabilities. In the years following the Bhopal accident, both state and federal environmental regulations were expanded to include mandatory preparedness to handle spills and releases on land, water, or air. These regulations include measures for emergency response such as communication and coordination with local health and law enforcement facilities, as well as community leaders and others. In addition, employers are now required to inform any workers in contact with hazardous materials of the nature and types of hazards to which they are exposed; they are also required to train them in emergency health and safety measures.

The disaster at Bhopal raises a number of critical issues and highlights the wide gulf between developed and developing countries in regard to design and maintenance standards for health and safety. Management decisions allowed the Bhopal plant to operate in an unsafe manner and for a shanty-town to develop around its perimeter without appropriate emergency planning. The Indian government, like many other developing nations in need of foreign investment, appeared to sacrifice worker safety in order to attract and keep Union Carbide and other industries within its borders. While a number of environmental and occupational health and safety standards existed in India before the accident, their inspection and enforcement was cursory or nonexistent. Often understaffed, the responsible Indian regulatory agencies were rife with corruption as well. The Bhopal disaster also raised questions concerning the moral and legal responsibilities of American companies abroad, and the willingness of those corporations to apply stringent United States safety and environmental standards to their operations in the **Third World** despite the relatively free hand given them by local governments.

Although worldwide shock at the Bhopal accident has largely faded, the suffering of many victims continues. While many national and international safeguards on the manufacture and handling of hazardous **chemicals** have been instituted, few expect that lasting improvements will occur in developing countries without a gradual recognition of the

Union Carbide plant in Bhopal, India. (Corbis-Bettmann. Reproduced by permission.)

economic and political values of stringent health and safety standards.

Bikini atoll

The primary objective of the Manhattan Project during World War II was the creation of a **nuclear fission** or atomic bomb. Even before that goal was accomplished in 1945, however, some nuclear scientists were thinking about the next step in the development of **nuclear weapons**, a fusion or **hydrogen** bomb.

Progress on a fusion bomb was slow. Questions were raised about the technical possibility of making such a bomb, as well as the moral issues raised by the use of such a destructive weapon. But the detonation of an atomic bomb by the Soviet Union in 1949 placed the fusion bomb in a new perspective. Concerned that the United States was falling behind in its arms race with the Soviet Union, President Harry S. Truman authorized a full-scale program for the development of a fusion weapon.

The first test of a fusion device occurred on October 31, 1952, at Eniwetok Atoll in the Marshall Islands in the Pacific Ocean. This was followed by a series of six more tests, code-named "Operation Castle," at Bikini Atoll in 1954. Two years later, on May 20, 1956, the first **nuclear fusion** bomb was dropped from an airplane over Bikini Atoll.

Bikini Atoll had been selected in late 1945 as the site for a number of tests of fission weapons, to experiment with different designs for the bomb and to test its effects on ships and the natural **environment**.

At that time, 161 people belonging to 11 families lived on Bikini. Since the Bikinians have no written history, little is known about their background. According to their oral tradition, the original home of their ancestors is nearby Wotje Atoll. Until the early 1900s, they had relatively little contact with strangers and were regarded with some disdain even by other Marshall Islanders. After the arrival of missionaries early in the twentieth century, the Bikinians became devout Christians. People lived on coconuts, breadfruits, arrowroot, fish, turtle eggs, and birds, all available in abundance on the atoll. The Bikinians were expert sailors and fishermen. Land ownership was important in the culture, and anyone who had no land was regarded as lacking in dignity.

On January 10, 1946, President Truman signed an order authorizing the transfer of everyone living on Bikini Atoll to the nearly uninhabited Bongerik Atoll. The United States Government asked the Bikinians to give up their native land to allow experiments that would bring benefit to all humankind. Such an action, the Americans argued, would earn for the Bikinians special glory in heaven. The islanders agreed to the request and, along with their homes, church, and community hall, were transported by the United States Navy to Rongerik.

In June and July of 1946, two tests of atomic bombs were conducted at Bikini as part of "Operation Crossroads." More than 90 vessels, including captured German and Japanese ships along with surplus cruisers, destroyers, submarines, and amphibious craft from the United States Navy, were assembled. Following these tests, however, the Navy concluded that Bikini was too small and moved future experiments to Eniwetok Atoll.

The testing of a nuclear fusion device in Operation Castle marked the return of bomb testing to Bikini. The most memorable test of that series took place in 1954 and was code-named "Bravo." Experts expected a yield of six megatons from the hydrogen bomb used in the test, but measured instead a yield of 15 megatons, 250% greater. Bravo turned out to be the largest single explosion in all of human history, producing an explosive force greater than all of the bombs used in all the previous wars in history.

Fallout from Bravo was consequently much larger than had been anticipated. In addition, because of a shift in wind patterns, the fallout spread across an area of about 50,000 mi^2 (11.5 km^2), including three inhabited islands—Rongelap, Itrik, and Rongerik. A number of people living on these islands developed radiation burns and many were evacuated from their homes temporarily. Farther to the east, a Japanese fishing boat which had accidentally sailed into the restricted zone was showered with fallout. By the time the boat returned to Japan, 23 crew members had developed **radiation sickness**. One eventually died of infectious hepatitis, probably because of the numerous blood transfusions he received.

The value of Bikini as a test site ended in 1963 when the United States and the Soviet Union signed the Limited Test Ban Treaty which outlawed nuclear weapons testing in the **atmosphere**, the oceans, and outer space. Five years later, the United States government decided that it was safe for the Bikinians to return home. By 1971, some had once again take up residence on their home island. Their return was short-lived. In 1978, tests showed that returnees had ingested quantities of radioactive materials much higher than the levels considered to be safe. The Bikinians were relocated once again, this time to the isolated and desolate island of Kili, 500 mi (804 km) from Bikini.

The primary culprit on Bikini was the radioactive **isotope** cesium-137. It had become so widely distributed in the **soil**, the water, and the crops on the island that no one living there could escape from it. With a half life of 30 years, the isotope is likely to make the island uninhabitable for another century.

Two solutions for this problem have been suggested. The brute-force approach is to scrape off the upper 12 in (30 cm) of soil, transport it to some uninhabited island, and bury it under concrete. A similar burial site, the "Cactus Crater," already exists on Runit Island. It holds radioactive wastes removed from Eniwetok Atoll. The cost of clearing off Bikini's 560 acres (227 ha) and destroying all its vegetation (including 25,000 trees) has been estimated at more then $80 million. A second approach is more subtle and makes use of chemical principles. Since potassium replaces cesium in soil, scientists hope that adding potassium-rich fertilizers to Bikini's soil will leach out the dangerous cesium-137.

At the thirtieth anniversary of Bravo, the Bikinians had still not returned to their home island. Many of the original 116 evacuees had already died. A majority of the 1,300 Bikinians who then lived on Kili no longer wanted to return to their native land. If given the choice, most wanted to make Maui, Hawaii, their new home. But they did not have that choice. The United States continues to insist that they remain somewhere in the Marshall Islands. The only place there they can't go, at least within most of their lifetimes, is Bikini Atoll.

Bioaccumulation

The general term for describing the accumulation of **chemicals** in the tissue of organisms. The chemicals that bioaccumulate are most often organic chemicals that are very soluble in fat and lipids and are slow to degrade. Usually used in reference to aquatic organisms, bioaccumulation occurs from exposure to contaminated water (e.g., gill uptake by fish) or by consuming food that has accumulated the chemical (e.g., **food chain/web** transfer). Bioaccumulation of chemicals in fish has resulted in public health consumption advisories in some areas, and has affected the health of certain fish-eating **wildlife** including eagles, cormorants, terns, and mink.

Bioaerosols

Bioaerosols are airborne particles derived from plants, animals or are living organisms, including viruses, bacteria, **fungi**, and mammal and bird antigens. Bioaerosols can range in size from roughly 0.01 micrometer (**virus**) to 100 micrometer (pollen). These particles can be inhaled and can cause many types of health problems, including allergic reactions (specific activation of the immune system), infectious disease (pathogens that invade human tissues), and toxic effects (due to biologically produced chemical **toxins**). The most common outdoor bioaerosols are pollens from grasses, trees, weeds, and crops. The most common indoor biological pollutants are animal dander (minute scales from hair, feathers, or skin), dust mite and cockroach parts, fungi (molds), infectious agents (bacteria and viruses), and pollen.

Bioassay

Bioassay refers to an evaluation of the toxicity of an **effluent** or other material on living organisms such as fish, rats, insects, bacteria, or other life forms. The bioassay may be used for many purposes, including the determination of: 1) permissible **wastewater discharge** rates; 2) the relative sensitivities of various animals; 3) the effects of physicochemical parameters on toxicity; 4) the compliance of discharges with effluent guidelines; 5) the suitability of a drug; 6) the safety of an **environment**; and 7) possible synergistic or antagonistic effects.

There are those who wish to reserve the term simply for the evaluation of the potency of substances such as drugs and vitamins, but the term is commonly used as described above. Of course, there are times when it is inappropriate to use bioassay and evaluation of toxicity synonymously, as when the goal of the assay is not to evaluate toxicity.

Bioassays are conducted as static, renewal, or continuous-flow experiments. In static tests, the medium (air or water) about the test organisms is not changed, in renewal tests the medium is changed periodically, and in continuous-flow experiments the medium is renewed continuously. When testing **chemicals** or wastewaters that are unstable, continuous-flow testing is preferable. Examples of instability include the rapid degradation of a chemical, significant losses in **dissolved oxygen**, problems with volatility, and precipitation.

Bioassays are also classified on the basis of duration. The tests may be short-term or acute, intermediate-term, or long-term, also referred to as chronic. In addition, aquatic toxicologists speak of partial- or complete- life-cycle assessments. The experimental design of a bioassay is in part reflected in such labels as range-finding, which is used for preliminary tests to approximate toxicity; screening for tests to determine if toxicity is likely by using one concentration and several replicates; and definitive, for tests to establish a particular end point with several concentrations and replicates).

The results of bioassays are reported in a number of ways. Early aquatic toxicity data were reported in terms of tolerance limits (TL). The term has been superseded by other terms such as effective concentration (EC), inhibiting concentration (IC), and lethal concentration (LC). The results of tests in which an animal is dosed (fed or injected) are reported in terms of effective dosage (ED) or lethal dosage (LD). When the potency of a drug is being studied, a therapeutic index (TI) is sometimes reported, which is the dose needed to cause a certain desirable effect (ED) divided by the lethal dose (LD) or some other ED. Median doses, the amount needed to affect 50% of the test population, are not always used. Needless to say, an evaluation of the response of a control population of organisms not exposed to a test agent or solution during the course of an experiment is very important.

Quality assurance and quality control procedures have become a very important part of bioassay methods. For example, the U.S. **Environmental Protection Agency** (EPA) has very specifically outlined how various aquatic bioassay procedures are to be performed and standardized to enhance reliability, **precision**, and **accuracy**. Other agencies in the United States and around the world have also worked very hard in recent years to standardize and improve quality assurance and control guidelines for the various bioassay techniques.

Bioassessment

According to the official definition of the United States **Environmental Protection Agency** (EPA), bioassessment refers to the process of evaluating the biological condition of a body of water using biological surveys (biosurveys) and other direct measurements of the resident biota—those organisms living in the surface water, including fish, insects, algae, plants and others. Since 1972 when the **Clean Water Act** was passed by Congress in order to clean up America's polluted waterways, the biological integrity of the nation's bodies of water has been the focus of professionals and citizens in ensuring the success of reaching this goal.

The derivation of biocriteria emerges from the bioassessment, and offers a narrative or numeric expression that explains the life surviving in the water. The process of evaluating biocriteria can be in "scores" using a method known as the ***Ohio multimetric*** approach; or, reported in "clusters" according to the ***Maine statistical*** approach.

Particularly in the study of **water pollution**, and the examininations of ways to correct it, a bioassessment of a body of water measures the composition, diversity, and functional organization of the community living in it. Consequently it lays the groundwork for the biocriteria in the determination of the quality of the desired goal in regard to the condition of the resource, and to what maximum level of management that water can be maintained. The result is not how extensive the pollutant level can be. The result of any bioassessment should be that the unique members of this community of living organisms thrive as they interact with the various elements of their common home. Biocriteria must be maintained separately from any chemical evaluation, whose *whole effluent toxicity* (WET) is a distinct measurement, and plays a different role in water management, along with the physical and toxicity factors also included in a complete **water quality** management program.

Measuring biological integrity is accomplished most successfully when researchers utilize the *Rapid Bioassessment Protocols* (RBPs) established originally in the 1980s by the EPA, and revised and reissued in 1999. The concept at the core of these protocols according to the official EPA information are:

- Cost-effective, scientifically valid procedures for biological surveys
- Provisions for multiple site investigations in a field season
- Quick turn-around of results for management decisions
- Scientific reports easily translated to management and the public

These RBPs resulted from those methods already in use by several state agencies. They are useful in the following areas of study:

- Determining if a stream is supporting a designated aquatic life use specified in state water quality standards
- Characterizing the existence and severity of impppairment to the water resource
- Helping to identify the sources and causes of impairment
- Evaluating the effectiveness of control actions and restoration activities
- Supporting use attainability studies an cumulative impact assessment
- Characterizing regional biotic attributes of reference conditions.

Not only are current living conditions key factors in studying this aquatic life. Physical and biological elements known as stressors are those that exert a negative or adverse effect on the organisms. How those stressors might have affected the organisms over a long period of time is crucial to understanding what actions will be necessary to improve the **ecology** of the waterbody.

Centers and groups for bioassessment are active in each state throughout the United States, and throughout the world. They operate with scientifical professionals such as biologists, as well as include trained citizen groups who participate by volunteering their time to monitor local water conditions. In one such program begun in California in 1998, trained citizen groups throughout the state under the training and guidance of a water biologist with the California Department of Fish and Game (CDFG) track the abundance and diversity of macroinvertebrates in order to assess the effects of **pollution**. This method was considered one of the best ways to monitor the health of streams and lakes due to the fact that each **species** is adapted to thrive in a particular habitat—along with an examination of bugs, whose various reactions to different types of pollutions have been monitored and well-established for years.

In an article written for the *EPA Journal,* in 1990, "Measuring Environmental Success," Steve Glomb noted that, "Biological community interactions are probably the most difficult goals to measure, Many scientists, however, think that these interactions are the most important factors to assess." Those interactions are often subtle, such as the example of invertebrates living in the mud on the floor of coastal waters, as Glomb mentioned. "Because they don't move much," he observed, "they can be used as an indication of problems over time." In determining past and current

living conditions, bioassessment has proved an invaluable tool in implementing the goals of clean water for all life, including humans.

Biocentrism

see **Environmental ethics**

Biochemical oxygen demand

The biochemical oxygen demand (BOD) test is an indirect measure of the **biodegradable** organic matter in an aqueous sample. The test is indirect because oxygen used by **microbes** as they degrade organic matter is measured, rather than the depletion of the organic materials themselves. Generally, the test is performed over a five-day period (BOD_5) at 68°F (20°C) in 10 fl oz (300 ml) bottles incubated in the dark to prevent interference from algal growth. **Dissolved oxygen** (DO) levels (in mg/l) are measured on day zero and at the end of the test. The following equation relates how the BOD_5 of a sample is calculated:

$$BOD_5, mg/L = \frac{(Do_{initial} - DO_{after\ 5\ days})}{mL\ sample}$$

Note that in the above equation "ml sample" refers to the amount of sample that is placed in a 300 ml BOD bottle. This is critical in doing a test because if too much sample is added to a BOD bottle, microbes will use all the DO in the water (i.e., $DO_{after\ 5\ days}=0$) and a BOD_5 cannot be calculated. Thus, the DO uptake at various dilutions of a given sample are made. One way of making the dilutions is to add different amounts of sample to different bottles. The bottles are then filled with dilution water which is saturated with oxygen, contains various nutrients, is at a neutral **pH**, and is very pure so as not to create any interference. Researchers attempt to identify a dilution which will provide for a DO uptake of greater than or equal to 2 mg/l and a DO residual of greater than or equal to 0.5–1.0 mg/l.

In some cases compounds or ions may be present in a sample that will inhibit microbes from degrading organic materials in the sample, thereby resulting in an artificially low or no BOD. Other times, the right number and/or types of microbes are not present, so the BOD is inaccurate. Samples may be "seeded" with microbes to compensate for these problems. The absence of a required **nutrient** will also make the BOD test invalid.

Thus, a number of factors can influence the BOD, and the test is known to be rather imprecise (i.e., values obtained vary by 10–15% of the actual value in a good test). However, the test continues to be a primary index of how well waters need to be treated or are treated and of the quality of natural waters. If wastes are not treated properly and contain too much BOD, the wastes may create serious oxygen deficits in environmental waters. The saturation concentration of oxygen in water varies somewhat with temperature and pressure but is often only in the area of 8–10 mg/l or less. To serve as a reference, the BOD_5 of raw, domestic **wastewater** ranges from about 100–300 mg/l. The demand for oxygen by the sewage is therefore clearly much greater than the amount of oxygen that water can hold in a dissolved form. To determine allowable BOD levels for a wastewater **discharge**, one must consider the relative flows/volumes of the wastewater and receiving (natural) water, temperature, reaeration of the natural water, biodegradation rate, input of other wastes, influence of benthic deposits and algae, DO levels of the wastewater and natural water, and condition/value of the receiving water.

Bioconcentration

see **Biomagnification**

Biodegradable

Biodegradable substances are those that can be decomposed quickly by the action of biological organisms, especially **microorganisms**. The term is a process by which materials or compounds are broken down to smaller components, and all living organisms participate to some degree. Foods, for instance, are degraded by living creatures to release energy and chemical constituents for growth. In the sense that the term is usually used, however, it has a more restricted meaning. It refers specifically to the breakdown of undesirable toxic and waste materials or compounds to harmless or tolerable ones. When breakdown results in the destruction of useful objects, it is referred to as biodeterioration.

Although the term has been in common use for only two or three decades, processes of biodegradation have been known and used for centuries. Some of the most familiar are **sewage treatment** of human wastes, **composting** of kitchen, garden and lawn wastes, and spreading of **animal waste** on farm fields. These processes, of course, all mitigate problems with common and ubiquitous byproducts of civilization. The variety of objectionable wastes has greatly increased as human society has become more complex. The **waste stream** now includes items such as plastic bottles, lubricants, and foam packaging. Many of the newer products are virtually non-biodegradable, or they degrade only at a very slow rate. In some instances biodegradability can be greatly enhanced by minor changes in the chemical composition of the product. Biodegradable containers and packaging have been developed that are just as functional for many purposes as their non-degradable counterparts.

Advances in the science of microbiology have greatly expanded the potential for biodegradation and have increased public interest. Examples of new developments include the discovery of hitherto unknown microorganisms capable of degrading crude oil, **petroleum hydrocarbons**, diesel fuel, **gasoline**, industrial solvents, and some forms of synthetic polymers and **plastics**. These discoveries have opened new approaches for cleansing the **environment** of the accumulating **toxins** and debris of human society. Unfortunately, the rate at which the new organisms attack exotic wastes is sometimes quite slow, and dependent on environmental conditions. Presumably, microorganisms have been exposed to common wastes of a very long time and have evolved efficient and rapid ways to attack and use them as food. On the other hand, there has not been sufficient time to develop equally efficient means for degrading the newer wastes.

Research continues on the surprising capabilities of the new **microbes** emphasizing opportunities for genetic control and manipulation of the unique metabolic pathways that make the organisms so valuable. The potential for biodegradation can be improved by increasing the rates at which wastes are attacked, and the range of environmental conditions in which degrading organisms can thrive. The advantages of biological cleanup agents are several. Non-biological techniques are often difficult and expensive. The traditional way of removing petroleum wastes from **soil**, for instance, has been to collect and incinerate it at high temperatures. This is very costly and sometimes impossible. The prospect of accomplishing the same thing by treating the **contaminated soil** with microorganisms without removing it from its location has much appeal. It should have less destructive impact on the contaminated site and be much less expensive.

Biodiversity

Biodiversity is an ecological notion that refers to the richness of biological types at a range of hierarchical levels, including: (1) genetic diversity within **species**, (2) the richness of species within communities, and (3) the richness of communities on landscapes. In the context of environmental studies, however, biodiversity usually refers to the richness of species in some geographic area, and how that richness may be endangered by human activities, especially through local or global **extinction**.

Extinction represents an irrevocable and highly regrettable loss of a portion of the biodiversity of Earth. Extinction can be a natural process, caused by: 1) random catastrophic events; 2) biological interactions such as **competition**, disease, and predation; 3) chronic stresses; or 4) frequent disturbance. However, with the recent ascendance of human activities as a dominant force behind environmental changes, there has been a dramatic increase in rates of extinction at local, regional, and even global levels.

The recent wave of **anthropogenic** extinctions includes such well-known cases as the **dodo**, **passenger pigeon**, great auk, and others. There are many other high-profile species that humans have brought to the brink of extinction, including the plains buffalo, **whooping crane**, eskimo curlew, **ivory-billed woodpecker**, and various ma-

rine mammals. Most of these instances were caused by an insatiable over-exploitation of species that were unable to sustain a high rate of **mortality**, often coupled with an intense disturbance of their **habitat**.

Beyond these tragic cases of extinction or endangerment of large, charismatic vertebrates, the earth's biota is experiencing an even more substantial loss of biodiversity caused by the loss of habitat. In part, this loss is due to the conversion of large areas of tropical ecosystems, particularly moist forest, to agricultural or otherwise ecologically degraded habitats. A large fraction of the biodiversity of tropical biomes is comprised of rare, endemic (i.e., with a local distribution) species. Consequently the conversion of **tropical rain forest** to habitats unsuitable for these specialized species inevitably causes the extinction of most of the locally endemic biota. Remarkably, the biodiversity of tropical forests is so large, particularly in insects, that most of it has not yet been identified taxonomically. We are therefore faced with the prospect of a **mass extinction** of perhaps millions of species before they have been recognized by science.

To date, about 1.7 million organisms have been identified and designated with a scientific name. About 6% of identified species live in boreal or polar latitudes, 59% in the temperate zones, and the remaining 35% in the tropics. The knowledge of the global richness of species is very incomplete, particularly in the tropics. If a conservative estimate is made of the number of unidentified tropical species, the fraction of global species that live in the tropics would increase to at least 86%.

Invertebrates comprise the largest number of described species, with insects making up the bulk of that total and beetles (*Coleoptera*) comprising most of the insects. Biologists believe that there still is a tremendous number of undescribed species of insects in the tropics, possibly as many as another 30 million species. This remarkable conclusion has emerged from experiments conducted by the entomologist Terry Erwin, in which scientists "fogged" tropical forest canopies and then collected the "rain" of dead arthropods. This research suggests that: (1) a large fraction of the insect biodiversity of tropical forests is undescribed; (2) most insect species are confined to a single type of forest, or even to particular plant species, both of which are restricted in distribution; and (3) most tropical forest insects have a very limited dispersal ability.

The biodiversity and endemism of other tropical forest biota are better known than that of arthropods. For example, a plot of only 0.2 acres (0.1 ha) in an Ecuadorian forest had 365 species of vascular plants. The richness of woody plants in tropical **rain forest** can approach 300 species per hectare, compared with fewer than 12–15 tree species in a typical temperate forest, and thirty to thirty-five species in the Great Smokies of the United States, the richest temperate forest in the world.

There have been few systematic studies of all of the biota of particular tropical communities. In one case, D. H. Janzen studied a savanna-like, 67-mi^2 (108-km^2) reserve of dry tropical forest in Costa Rica for several years. He estimated that the site had at least 700 plant species, 400 vertebrate species, and a remarkable 13,000 species of insect, including 3,140 species of moths and butterflies.

Why should one worry about the likelihood of extinction of so many **rare species** of tropical insects, or of many other rare species of plants and animals? There are three classes of reasons why extinctions are regrettable:

(1) There are important concerns in terms of the ethics of extinction. Central questions are whether humans have the "right" to act as the exterminator of unique and irrevocable species of **wildlife** and whether the human existence is somehow impoverished by the tragedy of extinction. These are philosophical issues that cannot be scientifically resolved, but it is certain that few people would applaud the extinction of unique species.

(2) There are utilitarian reasons. Humans must take advantage of other organisms in myriad ways for sustenance, medicine, shelter, and other purposes. If species become extinct, their unique services, be they biological, ecological, or otherwise, are no longer available for exploitation.

(3) The third class of reasons is ecological and involves the roles of species in maintaining the **stability** and integrity of ecosystems, i.e., in terms of preventing **erosion** and controlling **nutrient** cycling, productivity, trophic dynamics, and other aspects of **ecosystem** structure and function. Because we rarely have sufficient knowledge to evaluate the ecological "importance" of particular species, it is likely that an extraordinary number of species will disappear before their ecological roles are understood.

There are many cases where research on previously unexploited species of plants and animals has revealed the existence of products of great utility to humans, such as food or medicinals. One example is the rosy periwinkle (*Catharantus roseus*), a plant native to **Madagascar**. During a screening of many plants for possible anti-cancer properties, an extract of rosy periwinkle was found to counteract the reproduction of **cancer** cells. Research identified the active ingredients as several alkaloids, which are now used to prepare the important anti-cancer drugs vincristine and vinblastine. This once obscure plant now allows treatment of several previously incurable cancers and is the basis of a multi-million-dollar economy.

Undoubtedly, there is a tremendous, undiscovered wealth of other biological products that are of potential use to humans. Many of these natural products are present in

the biodiversity of tropical species that has not yet been "discovered" by taxonomists.

It is well known that extinction can be a natural process. In fact, most of the species that have ever lived on Earth are now extinct, having disappeared "naturally" for some reason or other. Perhaps they could not cope with changes in their inorganic or biotic **environment**, or they may have succumbed to some catastrophic event, such as a meteorite impact.

The rate of extinction has not been uniform over geological time. Long periods characterized by a slow and uniform rate of extinction have been punctuated by about nine catastrophic events of mass extinction. The most intense mass extinction occurred some 250 million years ago, when about 96% of marine species became extinct. Another example occurred 65 million years ago, when there were extinctions of many vertebrate species, including the reptilian orders Dinosauria and Pterosauria, but also of many plants and invertebrates, including about one half of the global **fauna** that existed then.

In modern times, however, humans are the dominant force causing extinction, mostly because of: (1) overharvesting; (2) effects of introduced predators, competitors, and diseases; and (3) habitat destruction. During the last 200 years, a global total of perhaps 100 species of mammals, 160 birds, and many other taxa are known to have become extinct through some human influence, in addition to untold numbers of undescribed, tropical species.

Even pre-industrial human societies caused extinctions. Stone-age humans are believed to have caused the extinctions of large-animal fauna in various places, by the unsustainable and insatiable **hunting** of vulnerable species in newly discovered islands and continents. Such events of mass extinction of large animals, co-incident with human colonization events, have occurred at various times during the last 10–50,000 years in Madagascar, New Zealand, **Australia**, Tasmania, Hawaii, North and South America, and elsewhere.

In more recent times, **overhunting** has caused the extinction of other large, vulnerable species, for example the flightless dodo (*Raphus cucullatus*) of Mauritius. Some North American examples include Labrador duck (*Camptorhynchus labradorium*), passenger pigeon (*Ectopistes migratorius*), Carolina parakeet (*Conuropsis carolinensis*), great auk (*Pinguinus impennis*), and Steller's sea cow (*Hydrodamalis stelleri*). Many other species have been brought to the brink of extinction by overhunting and loss of habitat. Some North American examples include eskimo curlew (*Numenius borealis*), plains **bison** (*Bison bison*), and a variety of marine mammals, including manatee (*Trichechus manatus*), right **whales** (*Eubalaena glacialis*), bowhead whale (*Balaena mysticetus*), and blue whale (*Balaenoptera musculus*).

Island biotas are especially prone to both natural and anthropogenic extinction. This syndrome can be illustrated by the case of the **Hawaiian Islands**, an ancient volcanic archipelago in the Pacific Ocean, about 994 mi (1,600 km) from the nearest island group and 2,484 mi (4,000 km) from the nearest continental landmass. At the time of colonization by Polynesians, there were at least 68 **endemic species** of Hawaiian birds, out of a total richness of land birds of 86 species. Of the initial 68 endemics, 24 are now extinct and 29 are perilously endangered. Especially hard hit has been an endemic family, the Hawaiian honeycreepers (Drepanididae), of which 13 species are believed extinct, and 12 endangered. More than 50 alien species of birds have been introduced to the Hawaiian Islands, but this gain hardly compensates for the loss and endangerment of specifically evolved endemics. Similarly, the native **flora** of the islands is estimated to have been comprised of 1,765–2,000 taxa of angiosperm plants, of which at least 94% were endemic. During the last two centuries, more than 100 native plants have become extinct, and the survival of at least an additional 500 taxa is threatened or endangered, some now being represented by only single individuals. The most important causes of extinction of Hawaiian biota have been the conversion of natural ecosystems to agricultural and urban landscapes, the introduction of alien predators, competitors, herbivores, and diseases, and to some extent, aboriginal overhunting of some species of bird.

Overhunting has been an important cause of extinction, but in modern times habitat destruction is the most important reason for the event of mass extinction that Earth's biodiversity is now experiencing. As was noted previously, most of the global biodiversity is comprised of millions of as yet undescribed taxa of tropical insects and other organisms. Because of the extreme endemism of most tropical biota, it is likely that many species will become extinct as a result of the clearing of natural tropical habitats, especially forest, and its conversion to other types of habitat.

The amount and rate of **deforestation** in the tropics are increasing rapidly, in contrast to the situation at higher latitudes where forest cover is relatively stable. Between the mid 1960s and the mid 1980s there was little change (less than 2%) in the forest area of North America, but in Central America forest cover decreased by 17%, and in South America by 7% (but by a larger%age in equatorial countries of South America). The global rate of clearing of tropical rain forest in the mid 1980s was equivalent to 6–8% of that **biome** per year, a rate that if projected into the future would predict a biome **half-life** of only nine to 12 years. Some of the cleared forest will regenerate through secondary **succession**, which would ultimately produce another mature forest. Little is known, however, about the rate and biological character

of succession in tropical rainforests, or how long it would take to restore a fully biodiverse ecosystem after disturbance.

The present rate of disturbance and conversion of tropical forest predicts grave consequences for global biodiversity. Because of a widespread awareness and concern about this important problem, much research and other activity has recently been directed towards the **conservation** and protection of tropical forests. As of 1985, several thousand sites, comprising more than 640,000 mi^2 (1 million km), had received some sort of "protection" in low-latitude countries. Of course the operational effectiveness of the protected status varies greatly, depending on the commitment of governments to these issues. Important factors include: (1) political stability; (2) political priorities; (3) finances available to mount effective programs to control **poaching** of animals and lumber and to prevent other disturbances; (4) the support of local peoples and communities for biodiversity programs; (5) the willingness of relatively wealthy nations to provide a measure of debt relief to impoverished tropical countries and thereby reduce their short term need to liquidate **natural resources** in order to raise capital and provide employment; and (6) local **population growth**, which also generates extreme pressures to over exploit natural resources.

The biodiversity crisis is a very real and very important aspect of the global environmental crisis. All nations have a responsibility to maintain biodiversity within their own jurisdictions and to aid nations with less economic and scientific capability to maintain their biodiversity on behalf of the entire planet. The modern biodiversity crisis focuses on species-rich tropical ecosystems, but the developed nations of temperate latitudes also have a large stake in the outcome and will have to substantially subsidize global conservation activities if these are to be successful. Much needs to be done, but an encouraging level of activity in the conservation and protection of biodiversity is beginning in many countries, including an emerging commitment by many nations to the conservation of threatened ecosystems in the tropics.

Biofilms

Marine microbiology began with the investigations of marine microfouling by L. E. Zobell and his colleagues in the 1930s and 1940s. Their interests focused primarily on the early stages of settlement and growth of **microorganisms**, primarily bacteria on solid substrates immersed in the sea. The interest in the study of marine microfouling was sporadic from that time until the early 1960s when interest in marine bacteriology began to increase. Since 1970 the research on the broad problems of bioadhesion and specifically the early stages of microfouling has expanded tremendously.

The initial step in marine fouling is the establishment of a complex film. This film, which is composed mainly of bacteria and diatoms plus secreted extracellular materials and debris, is most commonly referred to as the "primary film" but may also be called the "bacterial fouling layer," or "slime layer." The latter name is aptly descriptive since the film ultimately becomes thick enough to feel slippery or slimy to touch. In addition to the bacteria and diatoms that comprise most of the biota, the film may also include yeasts, **fungi**, and protozoans.

The settlement sequence in the formation of primary films is dependent upon a number of variables which may include the location of the surface, season of the year, depth, and proximity to previously fouled surfaces and other physiochemical factors.

Many studies have demonstrated the existence of some form of ecological **succession** in the formation of fouling communities, commencing with film forming microorganisms and reaching a climax community of macrofouling organisms such as barnacles, tunicates, mussels, and seaweeds.

Establishment of primary films in marine fouling has two functions: (a) to provide a surface favoring the settlement and adhesion of animal larvae and algal cells, and (b) to provide a **nutrient** source that could sustain or enhance the development of the fouling community.

Formation of a primary film is initiated by a phenomenon known as "molecular fouling" or "surface conditioning." The formation of this molecular film was first demonstrated by Zobell in 1943 and since has been confirmed by many other investigators. The molecular film forms by the **sorption** to solid surfaces of organic matter dissolved or suspended in seawater. The sorption of this dissolved material creates surface changes in the surface of the substrate which are favorable for establishing biological settlement. These dissolved organic materials originate from a variety of sources

such as end-products of bacterial decay, excretory products, dissolution from seaweeds, etc., and consist principally of sugars, amino acids, urea, and fatty acids.

This molecular film has been observed to form within minutes after any clean, solid surface is immersed in natural seawater. The role of this film in **biofouling** has been shown to modify the "critical surface tension" or wetability of the immersed surface which than facilitates the strong bonding of the microorganisms through the agency of mucopolysaccharides exuded by film-forming bacteria.

Bacteria have been found securely attached to substrates immersed in seawater after just a few hours. Initial colonization is by rod-shaped bacteria followed by stalked forms within 24–72 hours. As many as 40–50 **species** have been isolated from the surface of glass slides immersed in seawater for a few days.

Following the establishment of the initial film of bacteria and their secreted extracellular polymer on a solid substrate, additional bacteria and other microorganisms may attach. Most significant in this population are benthic diatoms but there are also varieties of filamentous microorganisms and protozoans. These organisms, together with debris and other organic particular matter that adhere to the surface create an intensely active biochemical **environment** and form the primary stage in the succession of a typical macrofouling community.

Considering the enormous economic consequences of marine fouling it is not at all surprising that there continues to be intense interest in the results of recent research, particularly in the conditions and processes of molecular film formation.

Biofiltration

Biofiltration refers to the removal and oxidation of organic gases (i.e., volatile organic compounds, or VOCs) from contaminated air by vapor phase biodegradation in beds (biofilters) of compost, **soil**, or other materials such as municipal waste, sand, bark peat, volcanic ash, or diatomaceous earth. As contaminated air (such as air from a soil vapor extraction process) flows through the biofilter, the VOCs sorb onto surfaces of the pile and are degraded by **microorganisms**. **Nutrient** blends or exogenous microbial cultures can be added to a biofilter to enhance its performance. Moisture needs to be continually supplied to the biofilter to counteract the drying effects of the gas stream. The stationary support media that make up the biofiltration bed should be porous enough to allow gas flow through the biofilter and should provide a large surface area with high wetting and sorptive capacities. This support media should also provide adequate buffering capacity and may also serve as a source of inorganic nutrients. Biofilters, also used to treat odors as well as organic contaminants, have been used in Europe for over twenty years. Compared to **incineration** and **carbon adsorption**, biofilters do not require landfilling of residuals or regeneration of spent materials.

Waste gases are moved through the units by induced or forced draft. Biofilters are capable of handling rapid air flow rates (e.g., up to 90,000 cubic ft (2,700 cubic m) per minute (cfm) in **filters** up to 20,000 sq ft (1,800 sq m) in wetted area) and VOC concentrations greater than 1,000 ppm. However, biofiltration removal of more highly halogenated compounds such as trichloroethylene (TCE) or carbon tetrachloride, which biodegrade very slowly under **aerobic** conditions, may require very long residence times (i.e., very large biofilters) or treatment of very low flow rates of air containing the contaminants.

The soil-type biofilter is similar in design to a soil compost pile. Fertilizers are preblended into the compost pile to provide nutrients for indigenous microorganisms, which accomplish the biodegradation of the VOCs. In the treatment bed type of biofilter, the waste air stream is humidified as it is passed through one or more beds of compost, municipal waste, sand, diatomaceous earth or other materials. Another type of biofilter is the disk biofilter, which consists of a series of humidified, compressed disks placed inside a reactor shell. These layered disks contain activated charcoal, nutrients, microbial cultures, and compost material. The waste air stream is passed through the disk system. Collected water condensate from the process is returned to the humidification system for **reuse**.

Biofouling

The term fouling, or more specifically biofouling, is used to describe the growth and accumulation of living organisms on the surfaces of submerged artificial structures as opposed to natural surfaces. Concern over and interest in fouling arises from practical considerations including the enormous costs resulting from fouling of ships, buoys, floats, pipes, cables and other underwater man-made structures.

From its first immersion in the sea, an artificial structure or surface changes through time as a result of a variety of influences including location, season and other physical and biological variables. Fouling communities growing on these structures are biological entities and must be understood developmentally. The development of a fouling community on a bare, artificial surface immersed in the sea displays a form of **succession**, similar to that seen in terrestrial ecosystems, which culminates in a community which may be considered a climax stage. Scientists have identified two distinct stages in fouling community development: 1) the primary or microfouling stage, and 2) the secondary or macrofouling stage.

Microfouling: When a structure is first submerged in seawater, **microorganisms**, primarily bacteria and diatoms, appear on the surface and multiply rapidly. Together with debris and other organic **particulate** matter, these microorganisms form a film on the surface. Although the evidence is not conclusive, it appears that the development of this film is a prerequisite to initiation of the fouling succession.

Macrofouling: The animals and plants that make up the next stages of succession in fouling communities are primarily the attached or sessile forms of animals and plants that occur naturally in shallow waters along the local coast. The development of fouling communities in the sea depends upon the ability of locally-occurring organism to live successfully in the new artificial **habitat**. The first organisms to attach to the microfouled surface are the swimming larvae of **species** present at the time of immersion. The kinds of larvae present vary with the season. Rapidly growing forms that become established first may ultimately be crowded out by others which grow more slowly. A comprehensive list of species making up fouling communities recorded from a wide variety of structures identified 2,000 species of animals and plants. Although the variety of organisms identified seems large it actually represents a very small proportion of the known marine species. Further, only about 50 to 100 species are commonly encountered in fouling, including bivalve mollusks (primarily oysters and mussels), barnacles, aquatic invertebrates in the phylum Bryozoa, tubeworms and other organisms in the class Polychaeta, and green and brown algae.

Control of fouling organisms has long been a formidable challenge resulting in the development and application of a wide variety of toxic paints and greases, or the use of metals which give off toxic ions as they corrode. However, none of the existing methods provide permanent control. Furthermore, the recognition of the potential environmental hazards attendant with the use of materials that leach **toxins** into the marine **environment** has led to the ban of some of the most widely used materials. This has stimulated efforts to develop alternative materials or methods of controlling biofouling that are environmentally safe.

Biogeochemistry

Biogeochemistry refers to the quantity and cycling of **chemicals** in ecosystems. Biogeochemistry can be studied at various spatial scales, ranging from communities, landscapes (or seascapes), and over Earth as a whole. Biogeochemistry involves the study of chemicals in organisms, and also in non-living components of the **environment**.

An important aspect of biogeochemistry is the fact that elements can occur in various molecular forms that can be transformed among each other, often as a result of biological reactions. Such transformations are an especially important consideration for nutrients, i.e., those chemicals that are required for the healthy functioning of organisms. As a result of biogeochemical cycling, nutrients can be used repeatedly–nutrients contained in dead **biomass** can be recycled through inorganic forms, back into living organisms, and so on. Biogeochemistry is also relevant to the movements and transformations of potentially toxic chemicals in ecosystems, such as metals, pesticides, and certain gases.

Nutrient Cycles

Ecologists have a good understanding of the biogeochemical cycling of the most important nutrients. These

include **carbon**, **nitrogen**, **phosphorus**, potassium, calcium, magnesium, and sulfur. Some of these can occur variously as gases in the **atmosphere**, as ions dissolved in water, in minerals in rocks and **soil**, and in a great variety of organic chemicals in the living or dead biomass of organisms. Ecologists study **nutrient** cycles by determining the quantities of the various chemical forms of nutrients in various compartments of ecosystems, and by determining the rates of transformation and cycling among the various compartments.

The **nitrogen cycle** is particularly well understood, and it can be used to illustrate the broader characteristics of nutrient cycling. Nitrogen is an important nutrient, being one of the most abundant elements in the tissues of organisms and a component of many kinds of biochemicals, including amino acids, proteins, and nucleic acids. Nitrogen is also one of the most common limiting factors to **primary productivity**, and the growth rates of plants in many ecosystems will increase markedly if they are fertilized with nitrogen. This is a fairly common characteristic of terrestrial and marine environments, and to a lesser degree of freshwater ones.

Plants assimilate most of their nitrogen from the soil environment, as nitrate (NO_3^-) or ammonium (NH_4^+) dissolved in the water that is taken up by roots. Some may also be taken up as gaseous **nitrogen oxides** (such as NO or NO_2) that are absorbed from the atmosphere. In addition, some plants live in a beneficial **symbiosis** with **microorganisms** that have the ability to fix atmospheric dinitrogen gas (N_2) into ammonia (NH_3), which can be used as a nutrient. In contrast, almost all animals satisfy their nutritional needs by eating plants or other animals and metabolically breaking down the organic forms of nitrogen, using the products (such as amino acids) to synthesize the necessary biochemicals of the animal. When plants and animals die, microorganisms active in the detrital cycle metabolize organic nitrogen in the dead biomass into simpler compounds, ultimately to ammonium.

The nitrogen cycle has always occurred naturally, but in modern times some of its aspects have been greatly modified by human influences. These include the fertilization of agricultural ecosystems, the dumping of nitrogen-containing sewage into lakes and other waterbodies, the **emission** of gaseous forms of nitrogen into the atmosphere, and the cultivation of nitrogen-fixing legumes. In some cases, human effects on nitrogen biogeochemistry result in increased productivity of crops, but in other cases serious ecological damages occur.

Toxic Chemicals in Ecosystems

Some human activities result in the release of toxic chemicals into the environment, which under certain conditions can pose risks to human health and cause serious damages to ecosystems. These damages are called **pollution**, whereas the mere presence of chemicals which cause no damage in the environment is referred to as contamination. Biogeochemistry is concerned with the emissions, transfers, and quantities of these potentially toxic chemicals in the environment and ecosystems.

Certain chemicals have a great ability to accumulate in organisms rather than in the non-living (or inorganic) components of the environment. This tendency is referred to as bioconcentration. Chemicals that strongly bioconcentrate include methylmercury and all of the persistent organochlorine compounds, such as **dichlorodiphenyl-trichloroethane** (DDT), **pentachlorophenol** (PCBs), dioxins, and **furans**. Methylmercury bioconcentrates because it is rather tightly bound in certain body organs of animals. The organochlorines bioconcentrate because they are extremely insoluble in water but highly soluble in fats and lipids, which are abundant in the bodies of organisms but not in non-living parts of the environment.

In addition, persistent organochlorines tend to occur in particularly large concentrations in the fat of top predators, that is, in animals high in the ecological food web, such as marine mammals, predatory birds, and humans. This happens because these chemicals are not easily metabolized into simpler compounds by these animals, so they accumulate in increasingly larger residues as the animals feed and age. This phenomenon is known as food-web magnification (or **biomagnification**). Food-web magnification causes chemicals such as DDT to achieve residues of tens or more **parts per million** (ppm) in the fatty tissues of top predators, even though they occur in the inorganic environment (such as water) in concentrations smaller than one part per billion (ppb). These high body residues can lead to ecotoxicological problems for top predators, some of which have declined in abundance because of their exposure to **chlorinated hydrocarbons**.

Because a few **species** of plants have an affinity for potentially toxic elements, they may bioaccumulate them to extremely high concentrations in their tissues. These plants are genetically adapted ecotypes which are themselves little affected by the residues, although they can cause toxicity to animals that might feed on their biomass. For example, some plants that live in environments in which the soil contains a mineral known as serpentine accumulate **nickel** to concentrations which may exceed thousands of ppm. Similarly, some plants (such as locoweed) growing in semi-arid environments can accumulate thousands of ppm of selenium in their tissues, which can poison animals that feed on the plants.

Biogeography

Biogeography is the study of the spatial distribution of plants and animals, both today and in the past. Developed during the course of nineteenth century efforts to explore, map, and describe the earth, biogeography asks questions about regional variations in the numbers and kinds of **species**: Where do various species occur and why? What physical and biotic factors limit or extend the range of a species? In what ways do species disperse (expand their ranges), and what barriers block their dispersal? How has species distribution changed over centuries or millennia, as shown in the fossil record? What controls the makeup of a **biotic community** (the combination of species that occur together)? Biogeography is an interdisciplinary science: many other fields, including paleontology, geology, botany, oceanography, and climatology, both contribute to biogeography and make use of ideas developed by biogeographers.

Because physical and biotic environments strongly influence species distribution, the study of **ecology** is closely tied to biogeography. Precipitation, temperature ranges, **soil** types, soil or water **salinity**, and insolation (exposure to the sun) are some elements of the physical **environment** that control the distribution of plants and animals. Biotic limits to distribution, constraints imposed by other living things, are equally important. Species interact in three general ways: **competition** with other species (for space, sunlight, water, or food), predation (e.g., an owl species relying on rodents for food), and **mutualism** (e.g., an insect pollenizing a plant while the plant provides nourishment for the insect). The presence or absence of a key plant or animal may function as an important control on another species' spatial distribution. **Community ecology**, the ways in which an assemblage of species coexist, is also important. Biotic communities have a variety of niches, from low to high trophic levels, from generalist roles to specialized ones. The presence or absence of species filling one of these roles influences the presence or survival of a species filling another role.

Two other factors that influence a region's biotic composition or the range of a particular species are dispersal, or spreading, of a species from one place to another; and barriers, environmental factors that block dispersal. In some cases a species can extend its range by gradually colonizing adjacent, hospitable areas. In other cases a species may cross a barrier, such as a mountain range, an ocean, or a **desert**, and establish a colony beyond that barrier. The cattle egret (*Bubulcus ibis*) exemplifies both types of movement. Late in the nineteenth century these birds crossed the formidable barrier of the Atlantic Ocean, perhaps in a storm, and established a breeding colony in Brazil. During the past one hundred years this small egret has found suitable **habitat** and gradually expanded its range around the coast of South America and into North America, so that by 1970 it had been seen from southern Chile to southern Ontario.

The study of dispersal has special significance in **island biogeography**. The central idea of island biogeography, proposed in 1967 by R. H. MacArthur and **Edward O. Wilson**, is that an island has an equilibrium number of species that increases with the size of the land mass and its proximity to other islands. Thus species diversity should be extensive on a large or nearshore island, with enough complexity to support large carnivores or species with very specific food or habitat requirements. Conversely, a small or distant island may support only small populations of a few species, with little complexity or **niche** specificity in the biotic community.

Principles of island biogeography have proven useful in the study of other "island" ecosystems, such as isolated lakes, small mountain ranges surrounded by deserts, and insular patches of forest left behind by clearcut **logging**. In such threatened areas as the Pacific Northwest and the Amazonian rain forests, foresters are being urged to leave larger stands of trees in closer proximity to each other so that species at high trophic levels and those with specialized food or habitat requirements (e.g., Northern spotted owls and Amazonian monkeys) might survive. In such areas as **Yellowstone National Park**, which national policy designates as an insular unit of habitat, the importance of adjacent habitat has received increased consideration. Recognition that clearcuts and farmland constitute barriers has led some planners to establish forest corridors to aid dispersal, enhance genetic diversity, and maintain biotic complexity in unsettled islands of natural habitat.

Biohydrometallurgy

Biohydrometallurgy is a technique by which **microorganisms** are used to recover certain metals from ores. The technique was first used over 300 years ago to extract **copper** from low-grade ores. In recent years, its use has been extended to the recovery of **uranium** and gold, and scientist believe that it will eventually be applied to the recovery of other metals such as **lead**, **nickel**, and zinc.

In most cases, biohydrometallurgy is employed when conventional mining procedures are too expensive or ineffective in recovering a metal. For example, dumps of unwanted waste materials are created when copper is mined by traditional methods. These wastes consist primarily of rock, gravel, sand, and other materials that are removed in order to reach the metal ore itself. But the wastes also contain very low concentrations (less than 0.5%) of copper ore.

Until recently, the concentrations of copper ore in a dump were too low to have any economic value. The cost of collecting the ore was much greater than the value of the copper extracted. But, as richer sources of copper ore are used up, low grade reserves (like dumps) become more attractive to mining companies. At this point, biohydrometallurgy can be used to leach out the very small quantities of ore remaining in waste materials.

The extraction of copper by means of biohydrometallurgy involves two types of reactions. In the first, microorganisms operate directly on compounds of copper. In the second, microorganisms operate on metallic compounds other than those of copper. These metallic compounds are then converted into forms which can, in turn, react with copper ores.

The use of biohydrometallurgical techniques on a copper ore waste dump typically begins by spraying the dump with dilute sulfuric **acid**. As the acid seeps into the dump, it creates an **environment** favorable to the growth of acid-loving microorganisms that attack copper ores. As the microorganisms metabolize the ores, they convert copper from an insoluble to a soluble form. Soluble copper is then leached out of the dump with sulfuric acid. It is recovered when the solution is pumped out to a recovery tank.

A second reaction occurs within the dump. Microorganisms also convert ferrous iron (Fe^{2+}) in ores such as pyrite (FeS_2) to ferric iron (Fe^{3+}). The ferric iron, in turn, oxidizes copper in the dump from an insoluble to a soluble form.

The mechanism described here is a highly efficient one. As microorganisms act on copper and iron compounds, they produce sulfuric acid as a by-product, thus enriching the environment in which they live. Ferric iron reduces and oxidizes copper at the same time, making the copper available for attack by microorganisms once again.

A number of microorganisms have been used in biohydrometallurgy. One of the most effective for the **leaching** of copper is *Thiobacillus ferrooxidans*. Research is now being conducted on the development of genetically engineered microorganisms that can be used in the recovery of copper and other metals.

The two other metals for which biohydrometallurgy seems to be most useful are uranium and gold. Waste dumps in South Africa and Canada have been treated to convert insoluble forms of uranium to soluble forms, allowing recovery by a method similar to that used with copper. In the treatment of gold ores, biohydrometallurgy is used in a pretreatment step prior to the conventional conversion of the metal to a cyanide-complex. The first commercial plants for the biohydrometallurgical treatment of gold ores are now in operations in South Africa and Zimbabwe.

Bioindicator

A bioindicator is a plant or animal **species** that is known to be particularly tolerant or sensitive to **pollution**. Based on the known association of an organism with a particular type or intensity of pollution, the presence of the organism can be used as a tool to indicate polluted conditions relative to unimpacted reference conditions. Sometimes a set of species or the structure and function of an entire **biological community** may function as a bioindicator. In assessing the impacts of pollution, bioindicators are frequently used to evaluate the "health" of an impacted **ecosystem** relative to a reference area or reference conditions. Field-based, site-specific environmental evaluations based on the bioindicator approach generally are complemented with laboratory studies of toxicity testing and **bioassay** experiments.

The use of individual species or a community structure as bioindicators involves the identification, classification and quantification of biota in the affected area. While many species are in use, the most widely used biological communities are the benthic macroinvertebrates. These are the sedentary and crawling worms and insect larvae that reside in the bottom sediments of aquatic systems such as lake and river bottoms. The bottom sediments usually contain most of the pollutants introduced into an aquatic system. Since these macroinvertebrates have limited mobility, they are continually exposed to the highest concentrations of pollutants in the system. Therefore, this benthic community is an ideal

bioindicator: stationary, localized and exposed to maximum pollutant concentrations within a specific location.

Often, alterations in community structure due to pollution include a change from a more diverse to a less diverse community with fewer species or taxa. The indicator community may also be composed mostly of species that are tolerant of or adapted to polluted conditions and pollution-sensitive species that are present upstream may be absent in the impacted zones. However, depending on the type of pollutant, the abundance of the pollution-tolerant species may be very high and, therefore, the size of the benthic community may be similar to or exceed the reference community upstream. This is common in cases where pollution from sewage discharges adds organic matter that provides food for some of the tolerant benthic species. In the case of toxic chemical (e.g., **heavy metals**, organic compounds) pollution, the benthic community may show an overall reduction both in diversity and abundance.

Tubificid worms are an example of pollution-tolerant indicator organisms. These worms live in the bottom sediments of streams and lakes and are highly tolerant of the kind of pollution that results from sewage discharges. In a river polluted by **wastewater discharge** from a **sewage treatment** plant, it is common to see a large increase in the number of tubificid worms in the stream sediments immediately downstream of the discharge. Upstream of the discharge, the number of these worms is much lower, reflecting the cleaner conditions. Further downstream, as the discharge is diluted, the number of tubificid worms again decreases to a level similar to the upstream portions of the river. Large populations of these worms dramatically demonstrate that pollution is present, and the location of these populations may also indicate the general area where the pollution enters the **environment**.

Alternatively, pollution-intolerant organisms can also be used to indicate polluted conditions. The larvae of mayflies live in stream sediments and are known to be particularly sensitive to pollution. In a river receiving wastewater discharge, mayflies show a pattern opposite to that of the tubificid worms. The mayfly larvae are normally present in large numbers above the discharge point, decrease or disappear at the discharge point (just where the tubificid worms are most abundant) and reappear further downstream as the effects of the discharge are diluted. In this case, the mayflies are pollution-sensitive indicator organisms and their absence serves as the indication of pollution. Similar examples of indicator organisms can be found among plants, fishes and other biological groups. Giant reedgrass (*Phragmites australis*) is a common marsh plant that is typically indicative of disturbed conditions in **wetlands**. Among fish, disturbed conditions may be indicated by the disappearance of sensitive species like trout which require clear, cold waters to thrive.

The usefulness of indicator organisms is unquestionable but limited. While their presence or absence provides a reliable general picture of polluted conditions, it is often difficult to identify clearly the exact sources of pollution, especially in areas with multiple sources of pollution. In the sediments of New York Harbor, for example, pollution-tolerant insect larvae are overwhelmingly dominant. However, it is impossible to attribute the large larval populations to just one of the numerous possible sources of pollution in this area which include ship traffic, sewage discharge, industrial discharge, and **storm runoff**. As more is learned about the physiology and life-history of an **indicator organism** and its response to different types of pollution, it may be possible to draw more specific conclusions.

Although the two terms are sometimes used interchangeably, indicator organisms should not be confused with monitor organisms (also called biomonitors) which are organisms that bioaccumulate toxic substances present in trace amounts in the environment. For example, when it is difficult to measure directly the low concentrations of a pollutant in water, chemical analysis of shellfish tissues from that location may show much higher, easily detected concentrations of that pollutant. In this case, the shellfish is used to monitor the level of the long-term presence of that pollutant in the area.

In the environmental field, bioindicators are commonly used in field investigations of contaminated sites to document impacts on the biological community and ecosystem. These studies are then followed up with focused laboratory tests to pinpoint the source of toxicity or stress. After clean-up and remedial actions have been implemented at a site, bioindicators are also used to track the effectiveness of the **remediation** activity. In the future, bioindicators may be used more widely as investigative and decision-making tools from the initial pollution and impact assessment stage to the remediation and post-remediation monitoring stages.

Biological community

A biological community is an association or assemblage of populations of organisms living in a localized area or **habitat**. The community is a level of organization incorporating individual organisms, **species**, and populations. A population is an assemblage of one species, and the community is a collage of one or more populations. Communities may be

large or small, ranging from the microscopic to the level of **biome** and **biosphere**.

"Community," as contrasted conceptually to **ecosystem**, does not necessarily include consideration of the physical **environment** or the habitat of a particular group of organisms, though it is of course impossible to understand fully the dynamics of a community without reference to the resources on which it exists. The term ecosystem was coined to incorporate study of a community together with its physical environment. Still, communities are adaptive systems, inseparable from and evolving in response to changing environmental conditions. So, the supply and availability of resources in the environment and also time are considerations in the dynamics of community structure and relationships. Individual communities may be relatively stable or in constant flux. Actual equilibrium may never exist but, even in approximation, it must be viewed as a dynamic state—the community in constant, subtle flux and change.

Biological communities are "interactional fields" characterized by a complicated set of interactions among complex assemblages, both within the locale and from without—including trophic relationships, the "who eats who" of energy exchanges. Interactions may be proximal or between locales (close by or quite widely separated), including intensive, extensive, or limited exchanges with the outside world. Organisms in communities interact both functionally and spatially or locationally, both "horizontally" and "vertically," interactions often independent of each other and not reducible to one or the other. Not all organisms necessarily interact with all the others, some may be almost totally uncoupled from some of the others and coexist relatively independently.

Most questions in **community ecology** focus on the "existence, importance, looseness, transience, and contingency of interactions." The degree to which these interactions result in meaningful biological patterns is still an open question—though particular communities are usually identified by some pattern of interactions, if only to set them off from others for the purposes of scientific study.

Biological fertility

The number of offspring produced by a female organism. In a population, biological fertility is measured as the general fertility rate (the birth rate multiplied by the number of sexually productive females) or as the total fertility rate (the lifetime average number of offspring per female). General dictionaries list fertility and **fecundity** as synonyms for reproductive fruitfulness. In **population biology**, biological fertility refers to the number of offspring actually produced, while fecundity is merely the biological ability to reproduce. Fecund individuals that fail to mate do not produce offspring (that is, are not biologically fertile), and do not contribute to **population growth**.

Biological integrity

see **Ecological integrity**

Biological magnification

see **Biomagnification**

Biological methylation

The process by which a methyl radical (-CH_3) is chemically combined with some other substance through the action of a living organism. One of the most environmentally important examples of this process is the **methylation** of **mercury** in the sediments of lakes, rivers, and other bodies of water. Elementary mercury and many of its inorganic compounds have relatively low toxicity because they are insoluble. However, in sediments, bacteria can convert mercury to an organic form, methylmercury, that is soluble in fat. When ingested by animals, methylmercury accumulates in body fat and exerts highly toxic, sometimes fatal, effects.

Biological oxygen demand

see **Biochemical oxygen demand**

Biological Resources Division

Created to assess, monitor, and research biological resources in United States, the Biological Resources Division (BRD) of the United States **Geological Survey** (USGS) is the non-regulatory biological research component of the United States Department of the Interior. First created in 1994 as the National Biological Survey (NBS), an independent agency within the **U.S. Department of the Interior**, the NBS was merged with the USGS (also part of the Interior Department) in 1996.

The BRD is the principal biological research and monitoring agency of the federal government. It is responsible for gathering, analyzing, and disseminating biological information in order to support sound management and stewardship of nation's biological and **natural resources**. It is also directed to foster understanding of biological systems and their benefits to society, and to make biological information available to the public. Although it was created mainly on the impetus of environmental and scientific organizations, the BRD also supports commercial and economic interests in that it seeks to identify opportunities for sustainable resource use. Agriculture and **biotechnology** are among the industries that stand to benefit from BRD research on new sources of food, fiber, and medicines.

Because it is independent of regulatory agencies—which are responsible for enforcing laws—the BRD has no formal regulatory, management, or enforcement roles. Therefore the BRD does not enforce laws such as the **Endangered Species Act**. Instead the BRD is responsible for gathering data that are scientifically sound and unbiased. The BRD also fosters public-private cooperation. For example, it worked with the International Paper Company in Alabama to develop a management plan for two **species** of pitcher plants found on company land that were candidates for the **Endangered Species** List. If it succeeds, this management plan will both preserve the pitcher plant populations—preventing the legal complications of having it listed as a federally endangered species—and allow continued judicious use of the land and resources.

The Biological Resources Division of the USGS was created in 1994 as an independent agency with the name National Biological Survey. The Survey was established on November 11, 1994, on the recommendations of President Bill Clinton and Interior Secretary Bruce Babbit. Renamed the National Biological Service (NBS) shortly after its creation, the agency was created by combining the biological research, inventory, and monitoring programs of seven agencies within the Department of the Interior. Built on the model of the Geological Survey, the NBS was established to provide accurate baseline data about ecosystems and species in United States territory. The mission of the NBS was to provide information to support sound stewardship of natural resources on public lands under the administration of the Department of the Interior. Part of its mission was also to foster cooperation among other entities involved in managing, monitoring, and researching natural resources. On October 1, 1996, the NBS was renamed the Biological Resources Division and merged with the United States Geological Survey. The USGS-BRD retains the research and information provision mandates of the NBS. Appointed as the first NBS/BRD director was H. Ronald Pulliam, a professor and research ecologist from of the Institute of Ecology and the University of Georgia in Athens.

The National Biological Service had a predecessor in the Bureau of Biological Survey, which operated as part of the Department of Agriculture from 1885–1939. The Bureau's first director, C. Hart Merriam, revolutionized biological collection techniques and in 15 years nearly quadrupled the number of known American mammal species. In 1939, the Bureau was transferred to the Department of the Interior, where it was the predecessor to the **Fish and Wildlife Service**. After its transfer to the Department of the Interior, the Bureau of Biological Survey's baseline data gathering and survey functions gradually diminished. The Fish and Wildlife Service now has regulatory and management responsibilities as well as research programs.

In recent years the need for a biological survey, and especially for the production of reliable baseline data, has resurfaced. The resurgence of interest in baseline data results in part from an interest in managing ecosystems, with a focus on stewardship and **ecosystem** restoration, in place of previous emphasis on individual species management. Managing and restoring ecosystems requires basic data and information on biological indicators, which are often unavailable. Interest in threatened and endangered species, and public participation in environmental organizations probably also contributed to the widespread support for establishing a biological survey.

The BRD is important because it is the only federal agency whose principal mission is to perform basic scientific, biological, and ecological research. As an explicitly scientific research body, the BRD works to incorporate current ecological theory in its research and monitoring programs. Central to the BRD's mission are ideas such as long-term stewardship of resources, maintaining **biodiversity**, identifying ecological services of biological resources, anticipating **climate** change, and restoring populations and habitats. Because of its emphasis on basic research the BRD can address current scientific themes that pertain to public policy such as fire ecology, **endocrine disruptors** (**chemicals** such as pentachlorophenols [PCBs] that interfere with endocrine and reproductive functions in animals), ecological roles of **wetlands**, and **habitat** restoration. The primary purpose of

this research activity is to provide land managers, especially within the Department of the Interior, with sound information to guide their management policies.

The BRD has two broad categories of research activities. One focus is on species for which the Department of Interior has trust responsibilities, including endangered species, marine mammals, migratory birds, and anadromous fish such as **salmon**. Research on these organisms involves studies of physiology, behavior, population dynamics, and **mortality**. The second general focus is on ecosystems. This class of research is directed at using experimentation, **modeling**, and observation to produce practical information concerning the complex interactions and functions of ecosystems, as well as human-induced changes in ecosystems.

In addition to these ecological research questions, the BRD is mandated to perform basic classification, mapping, and description functions. The division is responsible for classifying and mapping species within the United States, as well as prospecting for new species. It is also directed to develop a standard classification system for ecological units, biological indicators for **ecosystem health**, protocols for managing **pollution**, and guidelines for ecosystem restoration.

Part of this basic assessment function is a series of National Status and Trends Reports, to be released by the BRD every two years. These reports are to assess the health of biological resources and to report trends in their decline or improvement. The first two National Status and Trends Reports were released in 1995 and 1997. The 1995 report included more than 200 contributions on monitoring and population trends for plant, invertebrate, and vertebrate species, as well as summaries on the status of several biological communities and ecosystems. The 1997 report, published in two volumes, discusses factors such as natural processes, harvest exploitation, contaminants, **land use**, water use, nonindigenous species, and climate change that affect ecosystems in the United States. This status report also includes a major section discussing marine biological resources.

The USGS-BRD also provides a nationwide coordinated research agenda and a set of priorities for biological research. For example, it has undertaken a set of coordinated regional studies of the wide-ranging biological and ecological impacts of wetland distributions in Colorado, California, Texas, and other regions of the United States. Collectively these studies can provide a picture of nationwide trends and conditions, as well as producing coordinated information on restoration techniques, biodiversity issues, and biological indicators, at the same time as regional wetland problems are being addressed. Similar sets of coordinated studies have begun concerning the effects of endocrine-disrupting chemicals in the **environment** and on the use of prescribed fire as a management technique in a variety of ecosystems.

One of the principal mandates of the BRD is to distribute information. Free sharing of information is intended to maximize the usefulness of research findings. Part of the information sharing program includes substantial use of the Internet to distribute publications. Even the book-size National Status and Trends Reports are being published online to facilitate easy public access to their findings.

In addition to performing its own research the BRD provides coordination and a network of communication between federal agencies, state governments, universities, museums, and private **conservation** organizations. The National Partnership for Biological Survey, coordinated by the BRD, provides a network for sharing information and technology between federal, state, and other agencies. Participants in the Partnership include the United States **Forest Service**, the Natural Resources Conservation Service, the **National Oceanic and Atmospheric Administration**, the **Environmental Protection Agency**, the National Science Foundation, the Department of Defense, and the **Army Corps of Engineers**, as well as the Natural Heritage data centers and programs maintained by many states. The network of Natural Heritage programs is coordinated by **The Nature Conservancy**, a private organization dedicated to preserving habitat and species diversity. Also included in the Partnership are museums and universities nationwide that serve as repositories of information on biological resources and that conduct biological research, a range of non-governmental organizations, international conservation and research groups, Native American groups, private land holders, and resource user groups.

Biological treatment

see **Bioremediation**

Bioluminescence

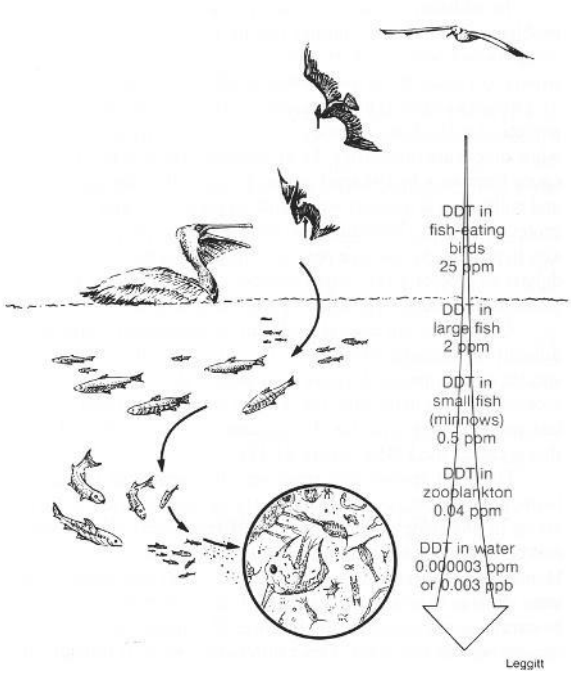
Bioluminescence ("living light") is the production of light by living organisms through a biochemical reaction. The

general reaction involves a substrate called luciferin and an **enzyme** called luciferase, and requires oxygen. Specifically, luciferin is oxidized by luciferase and the chemical energy produced is transformed into light energy. In **nature**, bioluminescence is fairly widespread among a diverse group of organisms such as bacteria, **fungi**, sponges, jellyfish, mollusks, crustaceans, some worms, fireflies, and fish. It is totally lacking in vertebrate animals. Fireflies are probably the most commonly recognized examples of bioluminescent organisms, using the emitted light for mate recognition.

Biomagnification

The **bioaccumulation** of **chemicals** in organisms beyond the concentration expected if the chemical was in equilibrium between the organism and its surroundings. Biomagnification can occur in both terrestrial and aquatic environments, but it is generally used in relation to aquatic situations. Most often, biomagnification occurs in the higher trophic levels of the **food chain/web**, where exposure to chemicals takes place mostly through food consumption rather than water uptake.

Biomagnification is a specific case of bioaccumulation and is different from bioconcentration. Bioaccumulation describes the accumulation of contaminants in the tissue of organisms. Typical examples of this include the elevated levels of many chlorinated pesticides and **mercury** in fish tissue. Bioconcentration is used to describe the concentration of a chemical in an organism from water uptake alone. This is quantitatively described by the bioconcentration factor, or BCF, which is the chemical concentration in tissue divided by the chemical concentration in water, expressed in equivalent units, at equilibrium. The vast majority of chemicals that bioaccumulate are aromatic organic compounds, particularly those with **chlorine** substituents. For organic compounds, the mechanism of bioaccumulation is thought to be the partitioning or solubilization of chemical into the lipids of the organism. Thus the BCF should be proportional to the lipophilicity of the chemical, which is described by the octanol-water partition coefficient, Kow. The latter is a physical-chemical property of the compound describing its relative solubility in an organic phase and is the ratio of its solubility in octanol to its solubility in water at equilibrium. It is constant at a given temperature. If one assumes that a chemical's solubility in octanol is similar to its solubility in lipid, then we can approximate the lipid-normalized BCF as equal to the Kow. This assumption has been shown to be a reasonable first approximation for most chemicals accumulation in fish tissue.



However, animals are exposed to contaminants by other routes in addition to passive partitioning from water. For instance, fish can take up chemicals from the food they eat. It has been noted in field collections that for certain chemicals, the observed fish-water ratio (BCF) is significantly greater than the theoretical BCF, based on Kow. This indicates that the chemical has accumulated to a greater extent than its equilibrium concentration. This is defined as biomagnification. This condition has been documented in aquatic animals, including fish, shellfish, **seals and sea lions**, **whales**, and otters, and in birds, mink, rodents, and humans in both laboratory and field studies.

The biomagnification factor, BMF, is usually described as the ratio of the observed lipid-normalized BCF to Kow, which is the theoretical lipid-normalized BCF. This is equivalent to the multiplication factor above the equilibrium concentration. If this ratio is equal to or less than one, then the compound has not biomagnified. If the ratio is greater than one, then the chemicals biomagnified by that factor. For instance, if a chemical's Kow were 100,000, then its lipid normalized BCF should be 100,000 if the chemical were in equilibrium in the organism's lipids. If the fish tissue concentration (normalized to lipids) were 500,000, then the chemical would be said to have biomagnified by a factor of five.

Biomagnification in the aquatic food chain often leads to biomagnification in terrestrial food chains, particularly in the case of bird and **wildlife** populations that feed on fish. Consider the following example that demonstrates the results of biomagnification. The concentrations of the insecticide dieldrin in various trophic levels are determined to be the following: water, 0.1 ng/L; **phytoplankton**, 100 ng/g lipid; **zooplankton**, 200 ng/g lipid; fish, 600 ng/g lipid; terns, 800 ng/g lipid. If the Kow were equal to one million, then the phytoplankton would be in equilibrium with the water, but the zooplankton would have magnified the compound by a factor of 2, the fish by a factor of 6, and the terns by a factor of 8.

The mechanism of biomagnification is not completely understood. To achieve a concentration of a chemical greater than its equilibrium value indicates that the elimination rate is slower than for chemicals that reach equilibrium. Transfer efficiencies of the chemical would affect the relative ratio of uptake and elimination. There are many factors that control the uptake and elimination of a chemical from the consumption of contaminated food, and these include factors specific to the chemical as well as factors specific to the organism. The chemical properties include solubility, Kow, molecular weight and volume, and diffusion rates between organism gut, blood, and lipid pools. The organism properties include the feeding rate, diet preferences, assimilation rate into the gut, rate of chemical's **metabolism**, rate of egestion, and

Biomagnification of the pesticide DDT in the food chain. DDT travels from runoff up through the food chain, accumulating in all exposed species. (McGraw-Hill Inc. Reproduced by permission.)

rate of organism growth. It is thought that the chemical's properties control whether biomagnification will occur, and that it is the transfer rate from lipid to blood that allows the chemical to attain a lipid concentration greater than its equilibrium value. Thus it follows that the chemicals that biomagnify have similar properties. They typically are organic; they have molecular weights between 200 and 600 daltons; they have Kows between 10,000 and 10 million; they are resistant to metabolism by the organism; they are non-ionic, neutral compounds; and they have molecular volumes between 260 and 760 cubic angstroms, a cross sectional width of less than 9.5 angstoms and a molecular surface area between 200 and 460 square angstroms. The latter dimensions allow them to more easily pass through lipid bilayers into cells but perhaps do not allow them to leave the cell easily due to their high lipophilicity. Since this disequilibrium would occur at each **trophic level**, it results in more and more biomagnification at each higher trophic level. Because humans occupy a very high trophic level, we are particularly vulnerable to adverse health effects as a result of exposure to chemicals that biomagnify.

Biomass

Biomass is a measure of the amount of biological substance minus its water content found at a given time and place on the earth's surface. Although sometimes defined strictly as living material, in actual practice the term often refers to living organisms, or parts of living organisms, as well as waste products or non-decomposed remains. It is a distinguishing feature of ecological systems and is usually presented as biomass density in units of dry weight per unit area. The term is somewhat imprecise in that it includes autotrophic plants, referred to as phytomass, heterotrophic **microbes**, and animal material, or zoomass. In most settings, phytomass is by far the most important component. A square meter of the planet's land area has, on average, about 22.05 – 26.46 lb (10 – 12 kg) of phytomass, although values may vary widely depending on the type of **biome**. Tropical rain forests average about 45 kg/m^2 while a **desert** biome may have a value near zero. The global average for heterotrophic biomass is approximately 0.1 kg/m^2, and the average for human biomass has been estimated at 0.5 g/m^2 if permanently glaciated areas are excluded.

The nature of biomass varies widely. Density of fresh material ranges from a low of 0.14 g/cm^3 for floats of aquatic plants to values greater that 1 g/cm^3 for very dense hardwood. The water content of fresh material may be as low as 5% in mature seeds or as high as 95% in fruits and young shoots. Water levels for living plants and animals run from 50 to 80%, depending on the **species**, season, and growing conditions. To insure a uniform basis for comparison, biomass samples are dried at 221°F (105°C) until they reach a constant weight.

Organic compounds typically constitute about 95% by weight of the total biomass, and nonvolatile residue, or ash, about 5%. **Carbon** is the principle element in biomass and usually represents about 45% of the total. An exception occurs in species that incorporate large amounts of inorganic elements such as silicon or calcium, in which case the carbon content may be much lower and nonvolatile residue several times higher. Another exception is found in tissues rich in

lipids (oil or fat), where the carbon content may reach values as high as 70%.

Photosynthesis is the principle agent for biomass production. Light energy is used by chlorophyll-containing green plants to remove (or fix) **carbon dioxide** from the **atmosphere** and convert it to energy rich organic compounds or biomass. It has been estimated that on the face of the earth approximately 200 billion tons of carbon dioxide are converted to biomass each year. Carbohydrates are usually the primary constituent of biomass, and cellulose is the single most important component. Starches are also important and predominate in storage organs such as tubers and rhizomes. Sugars reach high levels in fruits and in plants such as sugar cane and sugar beet. Lignin is a very significant non-carbohydrate constituent of woody plant biomass.

Biomass fuel

A **biomass** fuel is an energy source derived from living organisms. Most commonly it is plant residue, harvested, dried and burned, or further processed into solid, liquid, or gaseous fuels. The most familiar and widely used biomass fuel is wood. Agricultural waste, including materials such as the cereal straw, seed hulls, corn stalks and cobs, is also a significant source. Native shrubs and herbaceous plants are potential sources. **Animal waste**, although much less abundant overall, is a bountiful source in some areas.

Wood accounted for 25% of all energy used in the United States at the beginning of this century. With increased use of **fossil fuels**, its significance rapidly declined. By 1976, only 1–2% of United States energy was supplied by wood, and burning of tree wastes by the forest products industry accounted for most of it. Although the same trend has been evident in all industrialized countries, the decline has not been as dramatic everywhere. Sweden, for instance, still meets 8% of its energy needs with wood, and Finland, 15%.

Globally, it is estimated that biomass supplies about 6 or 7% of total energy, and it continues to be a very important energy source for many developing countries. In the last 15–20 years, interest in biomass has greatly increased even in countries where its use has drastically declined. In the United States rising fuel prices led to a large increase in the use of wood-burning stoves and furnaces for space heating. Impending fossil fuel shortages have greatly increased research on its use in the United States and elsewhere. Because biomass is a potentially renewable resource, it is recognized as a possible replacement of **petroleum** and **natural gas**.

Historically, burning has been the primary mode for using biomass, but because of its large water content it must be dried to burn effectively. In the field, the energy of the sun may be all that is needed to sufficiently lower its water level. When this is not sufficient, another energy source may be needed.

Biomass is not as concentrated an energy source as most fossil fuels even when it is thoroughly dry. Its density may be increased by milling and compressing dried residues. The resulting briquettes or pellets are also easier to handle, store, and transport. Compression has been used with a variety of materials including crop residues, herbaceous native plant material, sawdust, and other forest wastes.

Solid fuels are not as convenient or versatile as liquids or gases, and this is a drawback to the direct use of biomass. Fortunately, a number of techniques are known for converting it to liquid or gaseous forms.

Partial **combustion** is one method. In this procedure, biomass is burned in an **environment** with restricted oxygen. **Carbon monoxide** and **hydrogen** are formed instead of **carbon dioxide** and water. This mixture is called synthetic gas or "syngas." It can serve as fuel although its energy content is lower than natural gas (**methane**). Syngas may also be converted to **methanol**, a one carbon-alcohol that can be used as a **transportation** fuel. Because methanol is a liquid, it is easy to store and transport.

Anaerobic digestion is another method for forming gases from biomass. It uses **microorganisms**, in the absence of oxygen, to convert organic materials to methane. This method is particularly suitable for animal and human waste. Animal **feedlots** faced with disposal problems may install microbial gasifiers to convert waste to gaseous fuel used to heat farm buildings or generate electricity.

For materials rich in starch and sugar, fermentation is an attractive alternative. Through **acid** hydrolysis or enzymatic digestion, starch can be extracted and converted to sugars. Sugars can be fermented to produce **ethanol**, a liquid biofuel with many potential uses.

Cellulose is the single most important component of plant biomass. Like starch, it is made of linked sugar components that may be easily fermented when separated from the cellulose polymer. The complex structure of cellulose makes separation difficult, but enzymatic means are being developed to do so. Perfection of this technology will create a large potential for ethanol production using plant materials that are not human foods.

The efficiency with which biomass may be converted to ethanol or other convenient liquid or gaseous fuels is a major concern. Conversion generally requires appreciable energy. If an excessive amount of expensive fuel is used in the process, costs may be prohibitive. Corn (*Zea mays*) has been a particular focus of efficiency studies. Inputs for the corn system include energy for production and application of **fertilizer** and **pesticide**, tractor fuel, on-farm electricity, etc., as well as those more directly related to fermentation. A recent estimate puts the industry average for energy output at 133% of that needed for production and processing. This net energy gain of 33% includes credit for co-products such as corn oil and protein feed as well as the energy value of ethanol. The most efficient production and conversion systems are estimated to have a net energy gain of 87%. Although it is too soon to make an accurate assessment of the net energy gain for cellulose-based ethanol production, it has been estimated that a net energy gain of 145% is possible.

Biomass-derived gaseous and liquid fuels share many of the same characteristics as their fossil fuel counterparts. Once formed, they can be substituted in whole or in part for petroleum-derived products. **Gasohol**, a mixture of 10% ethanol in **gasoline**, is an example. Ethanol contains about 35% oxygen, much more than gasoline, and a gallon contains only 68% of the energy found in a gallon of gasoline. For this reason, motorists may notice a slight reduction in gas mileage when burning gasohol. However, automobiles burning mixtures of ethanol and gasoline have a lower exhaust temperature. This results in reduced toxic emissions, one reason that clean air advocates often favor gasohol use in urban areas.

Biomass is called as a renewable resource since green plants are essentially solar collectors that capture and store sunlight in the form of chemical energy. Its renewability assumes that source plants are grown under conditions where yields are sustainable over long periods of time. Obviously, this is not always the case, and care must be taken to insure that growing conditions are not degraded during biomass production.

A number of studies have attempted to estimate the global potential of biomass energy. Although the amount of sunlight reaching the earth's surface is substantial, less than a tenth of a percent of the total is actually captured and stored by plants. About half of it is reflected back to space. The rest serves to maintain global temperatures at life-sustaining levels. Other factors that contribute to the small fraction of the sun's energy that plants store include Antarctic and Arctic zones where little **photosynthesis** occurs, cold winters in temperate belts when plant growth is impossible, and lack of adequate water in **arid** regions. The global total net production of biomass energy has been estimated at 100 million megawatts per year per year. Forests and woodlands account for about 40% of the total, and oceans about 35%. Approximately 1% of all biomass is used as food by humans and other animals.

Soil requires some organic content to preserve structure and fertility. The amount required varies widely depending on **climate** and soil type. In tropical rain forests, for instance, most of the nutrients are found in living and decaying vegetation. In the interests of preserving photosynthetic potential, it is probably inadvisable to remove much if any organic matter from the soil. Likewise, in sandy soils, organic matter is needed to maintain fertility and increase water retention. Considering all the constraints on biomass harvesting, it has been estimated that about six million MWyr/yr of biomass are available for energy use. This represents about 60% of human society's total energy use and assumes that the planet is converted into a global garden with a carefully managed "photosphere."

Although biomass fuel potential is limited, it provides a basis for significantly reducing society's dependence on non-renewable reserves. Its potential is seriously diminished by factors that degrade growing conditions either globally or regionally. Thus, the impact of factors like global warming and **acid rain** must be taken into account to assess how well that potential might eventually be realized. It is in this context that one of the most important aspects of biomass fuel should be noted. Growing plants remove **carbon** dioxide from the **atmosphere** that is released back to the atmosphere when biomass fuels are used. Thus the overall concentration of atmospheric carbon dioxide should not change, and global warming should not result. Another environmental advantage arises from the fact that biomass contains much less sulfur than most fossil fuels. As a consequence, biomass fuels should reduce the impact of acid rain.

Biome

A large terrestrial **ecosystem** characterized by distinctive kinds of plants and animals and maintained by a distinct **climate** and **soil** conditions. To illustrate, the **desert** biome is characterized by low annual rainfall and high rates of evaporation, resulting in dry environmental conditions. Plants and animals that thrive in such conditions include cacti, brush, lizards, insects, and small rodents. Special adaptations, such as waxy plant leaves, allow organisms to survive under low moisture conditions. Other examples of biomes include **tropical rain forest**, arctic **tundra**, **grasslands**, temperate **deciduous forest**, **coniferous forest**, tropical **savanna**, and Mediterranean **chaparral**.

Biomonitoring

see **Bioindicator**

Biophilia

The term biophilia was coined by the American biologist, **Edward O. Wilson** (1929–), to mean "the innate tendency [of human beings] to focus on life and lifelike processes" and "connections that human beings subconsciously seek with the rest of life." Wilson first used the word in 1979 in an article published in the *New York Times Book Review*, and then in 1984 he wrote a short book (157 pages) that explored the notion in more detail.

Clearly, humans have coexisted with other **species** throughout our evolutionary history. In Wilson's view, this relationship has resulted in humans developing an innate, genetically based, or "hard-wired" need to be close to other species and to be empathetic to their needs. The presumed relationship is reciprocal, meaning other animals are also to varying degrees empathetic with the needs of humans. The biophilia hypothesis seems intuitively reasonable, although it is likely impossible that it could ever be proven universally correct. For instance, while many people may feel and express biophilia, some people may not.

There is a considerable body of psychological and medical evidence in support of the notion of biophilia, although most of it is anecdotal. There are, for example, many observations of sick or emotionally distressed people becoming well more quickly when given access to a calming natural **environment**, or when comforted by such pets as dogs and cats. There are also more general observations that many people are more comfortable in natural environments than in artificial ones — it can be much more pleasant to sit in a garden, for instance, than in a windowless room. The aesthetics and comfort of that room can, however, be improved by hanging pictures of animals or landscapes, by watching a nature show on television, or by providing a window that looks out onto a natural scene.

Wilson is a leading environmentalist and a compelling advocate of the need to conserve the threatened **biodiversity** of the world, such as imperiled natural ecosystems and **endangered species**. To a degree, his notion of biophilia provides a philosophical justification for **conservation** actions, by suggesting emotional and even spiritual dimensions to the human relationship with other species and the natural world. If biophilia is a real phenomenon and an integral part of what it is to be human, then our affinity for other species means that willful actions causing endangerment and **extinction** can be judged to be wrong and even immoral. Our innate affinity for other species provides an intrinsic justification for doing them no grievous harm, and in particular, for avoiding their extinction. It provides a justification for enlightened stewardship of the natural world.

Humans also utilize animals in agriculture (we raise them as food), in research, and as companions. Ethical considerations derived from biophilia provides a rationale for treating animals as well as possible in those uses, and may even be used to justify **vegetarianism** and anti-vivisectionism.

Bioregional Project

Based in the Ozark Mountains in Missouri, the Bioregional Project (BP) was founded in 1982 to promote the aims and interests of the bioregional movement in North America. Consisting primarily of a resource center designed to show people how to "come back home to Earth," the Bioregional Project is part of the international campaign to reshape culture and society according to ecological principles: "We work for the honor, protection and healing of the Earth, the Earth's people, and all the Earth's life."

A bioregion is what the group calls a "life region," an area determined by natural rather than historical or political boundaries. It is distinguished by the character of the **flora** and **fauna**, by the landforms, the types of rocks and soils,

Different biomes worldwide.

the **climate** in general, and by human habitation as it relates to this **environment**. The Bioregional Project emphasizes the natural logic of these boundaries, and it promotes the development of social and political institutions that take into account the interrelatedness of everything within them. They are working to increase the awareness that bioregions are "living, self-organizing systems," and they value humanity as one **species** among many. The Bioregional Project traces the roots of the movement to native and **indigenous peoples** and the "oldest Earth traditions." The group believes that ecological laws and principles form the basis of society and that the future survival of humanity depends on their ability to cooperate with the environment.

The Bioregional Project and the bioregional movement as a whole have strong ties to the international Green Movement, although bioregionalists consider themselves more "ecologically-centered." The **Greens** are oriented to urban areas, and they work for change in traditional political structures, operating within legislative as opposed to bioregional systems. The chief organizing tool of the bioregional movement is a model known as "the bioregional congress" or "green congress," where participants share information, develop ecological strategies, and draft planning programs and platform statements. The Bioregional Project convened the first bioregional congress in 1980 as the Ozark Community Congress (OACC), and it has since influenced both bioregional and green organizing throughout North America. The Project coordinated the first North American Bioregional Congress in 1984, an international assembly attended by over 200 people representing 130 organizations.

In addition to the assistance it provides for "those organizing bioregionally," the Bioregional Project also publishes books and pamphlets on **bioregionalism** and **ecology**. The organization sponsors lectures and educational presentations on these subjects as well. It supports research and lends technical assistance in a variety of areas from community economic development to **recycling**, **sustainable agriculture**, and forest protection. It is a subsidiary of the Ozarks Resource Center. Contact: Bioregional Project, Box 3, Brixley, MO 65618. telephone(417) 679 4773

[*Douglas Smith*]

Bioregionalism

Drawing heavily upon the cultures of **indigenous peoples**, bioregionalism is a philosophy of living that stresses harmony with **nature** and the integration of humans as part of the natural **ecosystem**. The keys to bioregionalism involve learning to live off the land, without damaging the **environment** or relying on heavy industrial machines or products. Bioregionalists believe that if the relationship between nature and humans improves, the society as a whole will benefit.

Environmentalists who practice this philosophy "claim" a bioregion or area. For example, one's place might be a **watershed**, a small mountain range, a particular area of the coast, or a specific **desert**. To develop a connection to the land and a **sense of place**, bioregionalists try to understand the natural history of the area as well as how it supports human life. For example, they study the plants and animals that inhabit the region, the geological features of the land, as well as the cultures of the people who live or have lived in the area.

Bioregionalism also stresses community life where participation, self-determination, and local control play important roles in protecting the environment. Various bioregional groups exist throughout the United States, ranging from the Gulf of Maine to the Ozark Mountains to the San Francisco Bay area. A North American Bioregional Congress loosely coordinates the bioregional movement.

Bioremediation

A number of processes for remediating contaminated soils and **groundwater** based on the use of **microorganisms** to convert contaminants to less hazardous substances. Most commercial bioremediation processes are intended to convert organic substances to **carbon dioxide** and water, although processes for addressing metals are under development. Many bacteria ubiquitously found in soils and groundwater are able to biodegrade a range of organic compounds. Compounds found in **nature**, and ones similar to those, such as **petroleum hydrocarbons**, are most readily biodegraded by these bacteria. Bioremediation of chlorinated solvents, polychlorinated biphenyl (PCB)s, pesticides, and many munitions compounds, while of great interest, is more difficult and has thus been much slower to reach commercialization.

In most bioremediation processes the bacteria use the contaminant as a food and energy source and thus survive and grow in numbers at the expense of the contaminant. In order to grow new cells, bacteria, like other biological **species**, require numerous minerals as well as **carbon** sources. These minerals are typically present in sufficient amounts

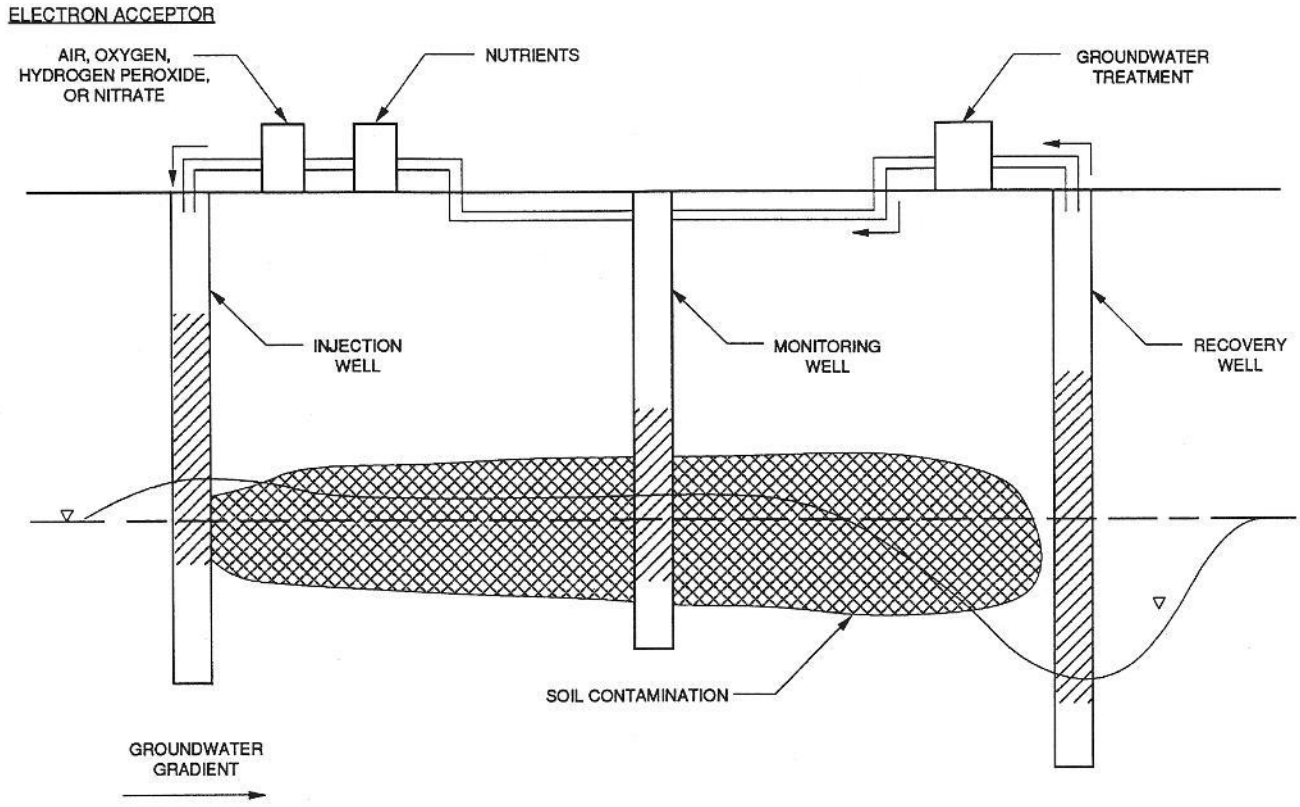
except for **phosphorus** and **nitrogen**, which are commonly added during bioremediation. If contaminant molecules are to be transformed, species called electron acceptors must also be present. By far the most commonly used electron acceptor is oxygen. Other electron acceptors include nitrate, sulfate, carbon dioxide, and iron. Processes that use oxygen are called **aerobic** biodegradation. Processes that use other electron acceptors are commonly lumped together as **anaerobic** biodegradation.

The vast majority of commercial bioremediation processes use aerobic biodegradation and thus include some method for providing oxygen. The amount of oxygen that must be provided depends not only on the mass of contaminant present but also on the extent of conversion of the contaminants to carbon dioxide and water, other sources of oxygen, and the extent to which the contaminants are physically removed from the soils or groundwater. Typically, designs are based on adding two to three pounds of oxygen for each pound of **biodegradable** contaminant.

The processes generally include the addition of **nutrient** (nitrogen and phosphorus) sources. The amount of nitrogen and phosphorus that must be provided is quite variable and frequently debated. In general, this amount is less than the 100:10:1 ratio of carbon to nitrogen to phosphorus of average cell compositions. It is also important to maintain the **soil** or groundwater **pH** near neutral (pH 6–8.5), moisture levels at or above 50% of **field capacity**, and temperatures between 39°F (4°C) and 95°F (35°C), preferably between 68°F (20°C) and 86°F (30°C).

Bioremediation can be applied in situ and ex situ by several methods. Each of these processes are basically engineering solutions to providing oxygen (or alternate electron acceptors) and possibly, nutrients to the contaminated soils, which already contain the bacteria. The addition of other bacteria is not typically needed or beneficial.

In situ processes have the advantage of causing minimal disruption to the site and can be used to address contamination under existing structures. In situ bioremediation to remediate aquifers contaminated with petroleum hydrocarbons such as **gasoline**, was pioneered in the 1970s and early 1980s by Richard L. Raymond and coworkers. These systems used groundwater recovery **wells** to capture contaminated water which was treated at the surface and reinjected after amendment with nutrients and oxygen. The nutrients consisted of ammonium chloride and phosphate salts and sometimes contained magnesium, manganese, and iron salts. Oxygen was introduced by sparging (bubbling) air into the reinjection water. As the injected water swept through the **aquifer**, oxygen and nutrients were carried to the contaminated soils and groundwater where the indigenous bacteria converted the hydrocarbons to new cell material, carbon dioxide, and water. Variations of this technology include the use of **hydrogen** peroxide as a source of oxygen and direct injection of air into the aquifer.



Bioremediation of soils located between the ground surface and the **water table** is most commonly practiced through **bioventing**. In this method, oxygen is introduced into the contaminated soils by either injecting air or extracting air from wells. The systems used are virtually the same as for vapor extraction. The major difference is in mode of operation and in the fact that nutrients are sometimes added by percolating nutrient amended water through the soil from the ground surface or buried horizontal pipes. Systems designed for bioremediation operate at low air flow rates to replace oxygen consumed during biodegradation and to minimize physical removal of volatile contaminants.

Bioremediation can be applied to excavated soils by landfarming, soil cell techniques, or in soil slurries. The simplest method is landfarming. In this method soils are spread to a depth of 12–18 inches (30–46 cm). Nutrients, usually commercial fertilizers with high nitrogen and low phosphorous content, are added periodically to the soils which are tilled or plowed frequently. In most instances, the treatment area is prepared by grading, laying down an impervious layer (clay or a synthetic liner), and adding a six-inch layer of clean soil or sand. Provisions for treating rainwater **runoff** are typically required. The frequent tilling and plowing breaks up soil clumps and exposes the soils and thus bacteria to air. This method is more suitable for treating silty and clayey soils than are most of the other methods. It is not generally appropriate for soils contaminated with volatile contaminants such as gasoline because vapors can not be controlled unless the process is conducted within a closed structure.

Excavated soils can also be treated in cells or piles. A synthetic liner is placed on a graded area and covered with sand or gravel to permit collection of runoff water. The sands or gravel are covered with a **permeable** fabric and nutrient amended soils are added. Slotted PVC pipe is added as the pile is built. The soils are covered with a synthetic liner and the PVC pipes are connected to a blower. Air is slowly extracted from the soils and, if necessary, treated before being discharged to the **atmosphere**. This method requires less room than landfarming and less maintenance during operations, and can be used to treat volatile contaminants because the vapors can be controlled.

Excavated soils can also be treated in soil/water slurries in either commercial reactors or in impoundments or lagoons. Soils are separated from oversize materials and mixed with water, nutrients are added, and the **slurry** is aerated to provide oxygen. In some cases additional sources of bacteria and/or surfactants are added. These systems are usually capable of attaining more rapid rates of biodegradation than other systems but have limited throughput.

Bioremediation of the saturated zone using hydrogen peroxide in the Raymond process.

Selection and design of a particular bioremediation method requires that the site be carefully investigated to define the lateral and horizontal extent of contamination including the total mass of biodegradable substances. Understanding the soil types and distribution and the site **hydrogeology** is as important as identifying the contaminants and their distribution in both soils and groundwater. Designing bioremediation systems requires the integration of microbiology, chemistry, hydrogeology, and engineering.

Bioremediation is generally viewed favorably by regulatory agencies and is actively supported by the U. S. **Environmental Protection Agency** (EPA). The mostly favorable publicity and the perception of bioremediation as a natural process has led to greater acceptance by the public compared to other technologies, such as **incineration**. It is expected that the use of bioremediation to treat soils and groundwater contaminated with petroleum hydrocarbons and other readily biodegradable compounds will continue to grow. Continued improvements in the design and engineering of bioremediation systems will result from the expanding use of bioremediation in a competitive market. It is anticipated that processes for treating the more recalcitrant organic compounds and metals will become commercial through greater understanding of microbiology and specific developments in the isolation of special bacteria and **genetic engineering**.

Biosequence

A sequence of soils that contain distinctly different **soil** horizons because of the influence that vegetation had on the soils during their development. A typical biosequence would be the **prairie** soils in a dry **environment**, oak-savannah soils as a transition zone, and forested soils in a wetter environment. Prairie soils have dark, thick surface horizons while forested soils have a thin, dark surface with a light-colored zone below.

Biosphere

The biosphere is the largest possible earthly organismic community. It is a terrestrial envelope of life, or the total global **biomass** of living matter. The biosphere incorporates every individual organism and **species** on the face of the earth—those that walk on the ground or live in the crevices of rock and down into the **soil**, those that swim in rivers, lakes, and oceans, and those that move in and out of the **atmosphere**.

Bios is the Greek word for life; "sphere" is from the Latin *sphaera*, which means essentially the "circuit or range of action, knowledge or influence," the "place or scene of action or existence," the "natural, normal or proper place." Combined into biosphere, the two ideas define the normal global place of existence for all earthly life-forms and, increasingly, a global area of influence and action for humans. Thinking of the mass of life forms on the earth as the biosphere also provides an impression of circular, cyclic systems and suggests a holistic concept of integration and unity.

A *Scientific American* book on the biosphere described it as "this thin film of air and water and soil and life no deeper than ten miles, or one four-hundredth of the earth's radius [that] is now the setting of the uncertain history of man." G. E. Hutchinson in that same book asked, "What is it that is so special about the biosphere?" He suggested that the answer seems to have three parts: "First, it is a region in which liquid water can exist in substantial quantities. Second, it receives an ample supply of energy from an external source, ultimately from the sun. And third, within it there are interfaces between the liquid, the solid and the gaseous states of matter." Both of these might better describe what LaMont Cole labeled the "ecosphere," the global ecosystem—the biosphere plus its abiotic **environment**. But the significance of Hutchinson's three-part statement is that those three characteristics of the earth's surface make it possible for life to exist. They provide the conditions necessary for the abundant and diverse organisms of the biosphere to live.

Life began in a very different environment than found today: the atmosphere, for example, was mostly **methane**, ammonia, and **carbon dioxide**. As life evolved, it changed the atmosphere (and other abiotic components of the surface of the earth), transforming it into the present oxygen-rich mixture of gases vital to life as it now exists. And those life-forms maintain that critical mixture in a complex, fluctuating system of global cycles.

The diversity and complexity of the biosphere is staggering. The accumulated human knowledge of its workings is prodigious, but even more impressive is the immense ignorance of that complexity. Humans have identified about 1.5 million living members of the biosphere and thus have some knowledge of at least that many. However, conservative estimates of the actual number of species begin at 3 or 3.5–5 million species. Recent and less conservative estimates range up to a possible 100 million. That means humans are totally ignorant of anywhere from 50% to as much as 98.5% of the other members of the earth's **biological community**. Their existence is suspected, but they cannot be identified or their existence documented by even a name.

One of the concerns about large-scale human ignorance of the biosphere is that many species might be extinguished before they are even known. Human activities, especially destruction of **habitat**, are increasing the normal rate of species **extinction**. The diversity of the biosphere may be diminishing rapidly.

Taxonomically, the biosphere is organized into five kingdoms: monera, protista, **fungi**, animalia, and plantae, and a multitude of subsets of these, including the multiple millions of species mentioned above. G. Piel estimates that of the 1,200–1,800 billion tons dry weight of the biosphere, most of it—some 99%—is plant material. All the life-forms in the other four taxons, including animals and obviously the five billion-plus humans alive today, are part of that less than one%.

The biosphere can also be subdivided into biomes: a **biome** incorporates a set of biotic communities within a particular region exposed to similar climatic conditions and which have dominant species with similar life cycles, adaptations, and structures. Deserts, **grasslands**, temperate deciduous forests, coniferous forests, **tundra**, tropical rain forests, tropical seasonal forests, freshwater biomes, estuaries, **wetlands**, and marine biomes, are examples of specific terrestrial or aquatic biomes.

Another indication of the complexity of the biosphere is a measure of the processes that take place within it, especially the essential processes of **photosynthesis** and **respiration**. The sheer size of the biosphere is indicated by the amount of biomass present. Vitousek and his colleagues estimate the net primary production of the earth's biosphere as 224.5 petagrams, one petagram being equivalent to 10^{15} grams.

The biosphere interacts in constant, intricate ways with other global systems: the atmosphere, lithosphere, hydrosphere, and pedosphere. Maintenance of life in the biosphere depends on this complex network of biological-biological, physical-physical, and biological-physical interactions. All the interactions are mediated by an equally complex system of positive and negative feedbacks—and the total makes up the dynamics of the whole system. Since each and all interpenetrate and react on each other constantly, outlining a global **ecology** is a major challenge.

Normally biospheric dynamics are in a rough balance. The **carbon cycle**, for example, is usually balanced between production and **decomposition**, the familiar equation of photosynthesis and respiration. As Piel notes: "The two planetary cycles of photosynthesis and **aerobic metabolism** in the biomass not only secure renewal of the biomass but also secure the steady-state mixture of gases in the atmosphere. Thereby, these life processes mediate the inflow and outflow of **solar energy** through the system; they screen out lethal radiation, and they keep the temperature of the planet in the narrow range compatible with life." But human activities, especially the **combustion** of **fossil fuels**, contribute to increases in **carbon** dioxide, distorting the balance and in the process changing other global relationships such as the **nature** of incoming and out-going radiation and differentials in temperature between poles and tropics.

If humans are to better understand the biosphere, many more studies must be undertaken on many levels. A number of levels of biological integration must be recognized and analyzed, each with different properties and each offering scholars special problems and special insights. The totality of the biosphere can be broken down in many different ways, but life extends from the single cell to the totality of the globe. Though biologists usually define their disciplines within the bounds of one level and though they may study only one level, scholars should recognize context, the full range of levels and the interactions between them.

Humans are, of course, one of the species that make up the living biosphere. *Homo sapiens* fits into the Linnean hierarchy on the primate branch. Using that hierarchy as a connective device, humans may take a first step toward understanding how they relate to the rest of the inhabitants of the biosphere, down to the most remote known species.

Humans are without doubt the dominant species in the biosphere. The transformation of radiant energy into useable biological energy is increasingly being diverted by humans to their own use. A common estimate is that humans are now diverting huge amounts of the net primary production of the globe to their own use: perhaps 40% of terrestrial production and close to 25% of all production is either utilized or wasted through human activity. Net primary production is defined as the amount of energy left after subtracting the respiration of primary producers, or plants, from the total amount of energy. It is the total amount of "food" available from the process of photosynthesis—the amount of biomass available to feed organisms, such as humans, that do not acquire food through photosynthesis.

Humans are displacing their neighbors in the biosphere through a multitude of activities: conversion of natural systems to agriculture, direct consumption of plants, consumption of plants by livestock, harvesting and conversion of forests, **desertification**, and many, many others. The biosphere is the source of all good: humans are an integral part of the biosphere and depend on its functioning for their well-being, for their very lives.

Biosphere reserve

A **biosphere** reserve is an area of land recognized and preserved for its ecological significance. Ideally biosphere reserves contain undisturbed, natural environments that represent some of the world's important ecological systems and communities. Biosphere reserves are established in the interest of preserving the genetic diversity of these ecological zones, supporting research and education, and aiding local, **sustainable development**. Official declaration and international recognition of biosphere reserve status is intended to protect ecologically significant areas from development and destruction. Since 1976 an international network of biosphere reserves has developed, with the sanction of the United Nations. Each biosphere reserve is proposed, reviewed, and established by a national biosphere reserve commission in the home country under United Nations guidelines. Communication among members of the international biosphere network helps reserve managers share data and compare management strategies and problems.

The idea of biosphere reserves first gained international recognition in 1973, when the United Nations Educational and Scientific Organization (UNESCO)'s **Man and**

the Biosphere Program (MAB) proposed that a worldwide effort be made to preserve islands of the world's living resources from **logging**, mining, urbanization, and other environmentally destructive human activities. The term derives from the ecological word "biosphere," which refers to the zone of air, land, and water at the surface of the earth that is occupied by living organisms. Growing concern over the survival of individual **species** in the 1970s and 1980s led increasingly to the recognition that **endangered species** could not be preserved in isolation. Rather, entire ecosystems, extensive communities of interdependent animals and plants, are needed for threatened species to survive. Another idea supporting the biosphere reserve concept was that of genetic diversity. Generally ecological systems and communities remain healthier and stronger if the diversity of resident species is high. An alarming rise in species extinctions in recent decades, closely linked to rapid **natural resources** consumption, led to an interest in genetic diversity for its own sake. Concern for such ecological principles as these led to UNESCO's proposal that international attention be given to preserving the earth's ecological systems, not just individual species.

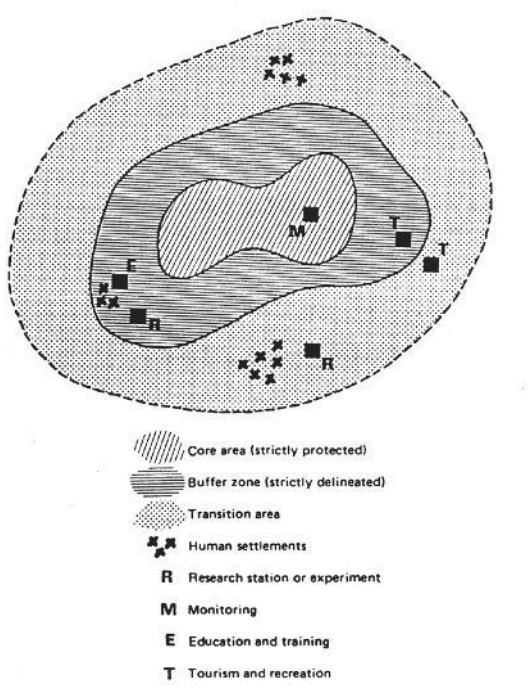
The first biosphere reserves were established in 1976. In that year, eight countries designated a total of 59 biosphere reserves representing ecosystems from **tropical rain forest** to temperate sea coast. The following year 22 more countries added another 72 reserves to the United Nations list, and by 2002 there was a network of 408 reserves established in 94 different countries.

Like national parks, **wildlife** refuges, and other **nature** preserves, the first biosphere reserves aimed to protect the natural **environment** from surrounding populations, as well as from urban or international exploitation. To a great extent this idea followed the model of United States national parks, whose resident populations were removed so that parks could approximate pristine, undisturbed natural environments.

But in smaller, poorer, or more crowded countries than the United States, this model of the depopulated reserve made little sense. Around most of the world's nature preserves, well-established populations—often indigenous or tribal groups—have lived with and among the area's **flora** and **fauna** for generations or centuries. In many cases, these groups exploit local resources—gathering nuts, collecting firewood, growing food—without damaging their environment. Sometimes, contrary to initial expectations, the activity of **indigenous peoples** proves essential in maintaining **habitat** and species diversity in preserves. Furthermore, local residents often possess an extensive and rare understanding of plant habitat and animal behavior, and their skills in using resources are both valuable and irreplaceable. At the very least, the cooperation and support of local populations is essential for the survival of parks in crowded or resource-poor countries. For these reasons, the additional objectives of local cooperation, education, and sustainable economic development were soon added to initial biosphere reserve goals of biological preservation and scientific research. Attention to humanitarian interests and economic development concerns today sets apart the biosphere reserve network from other types of nature preserves, which often garner resentment from local populations who feel excluded and abandoned when national parks are established. United Nations MAB guidelines encourage local participation in management and development of biosphere reserves, as well as in educational programs. Ideally, indigenous groups help administer reserve programs rather than being passive recipients of outside assistance or management.

In an attempt to mesh the diverse objectives of biosphere reserves, the MAB program has outlined a theoretical reserve model consisting of three zones, or concentric rings, with varying degrees of use. The innermost zone, the core, should be natural or minimally disturbed, essentially without human presence or activity. Ideally this is where the most diverse plant and animal communities live and where natural **ecosystem** functions persist without human intrusion. Surrounding the core is a **buffer** zone, mainly undisturbed but containing research sites, monitoring stations, and habitat **rehabilitation** experiments. The outermost ring of the biosphere reserve model is the transition zone. Here there may be sparse settlement, areas of traditional use activities, and tourist facilities.

Many biosphere reserves have been established in previously existing national parks or preserves. This is especially common in large or wealthy countries where well established park systems existed before the biosphere reserve idea was conceived. In 1991 most of the United States' 47 biosphere reserves lay in national parks or wildlife sanctuaries. In countries with few such preserves, nomination for United Nations biosphere reserve status can sometimes attract international assistance and funding. In some instances debt for nature swaps have aided biosphere reserve establishment. In such an exchange, international **conservation** organizations purchase part of a country's national debt for a portion of its face value, and in exchange that country agrees to preserve an ecologically valuable region from destruction. Bolivia's Beni Biosphere Reserve came about this way in 1987 when **Conservation International**, a Washington-based organization, paid $100,000 to Citicorp, an international lending institution. In exchange, Citicorp forgave $650,000 in Bolivian debt, loans the bank seemed unlikely to ever recover, and Bolivia agreed to set aside a valuable tropical mahogany forest. This process has also produced other reserves, including Costa Rica's La Amistad, and Ecuador's Yasuni and Galapagos Biosphere Reserves.



In practice, biosphere reserves function well only if they have adequate funding and strong support from national leaders, legislatures, and institutions. Without legal protection and long-term support from the government and its institutions, reserves have no real defense against development interests.

National parks can provide a convenient institutional niche, defended by national laws and public policing agencies, for biosphere reserves. Pre-existing wildlife preserves and game sanctuaries likewise ensure legal and institutional support. Infrastructure—management facilities, access roads, research stations, and trained wardens—is usually already available when biosphere reserves are established in or adjacent to ready-made preserves.

Funding is also more readily available when an established **national park** or game preserve, with a pre-existing operating budget, provides space for a biosphere reserve. With intense competition from commercial loggers, miners, and developers, money is essential for reserve survival. Especially in poorer countries, international experience increasingly shows that unless there is a reliable budget for management and education, nearby residents do not learn cooperative reserve management, nor do they necessarily support the reserve's presence. Without funding for policing and legal defense, development pressures can easily continue to threaten biosphere reserves. Logging, clearing, and destruction often continue despite an international agreement on paper that resource extraction should cease. Turning parks into biosphere reserves may not always be a good idea. National park administrators in some less wealthy countries fear that biosphere reserve guidelines, with their compromising objectives and strong humanitarian interests, may weaken the mandate of national parks and wildlife sanctuaries set aside to protect endangered species from population pressures and development. In some cases, they argue, there exists a legitimate need to exclude people if **rare species** such as **tigers** or **rhinoceroses** are to survive.

Because of the expense and institutional difficulties of establishing and maintaining biosphere reserves, about two-thirds of the world's reserves exist in the wealthy and highly developed nations of North America and Europe. Poorer countries of Africa, Asia, and South America have some of the most important remaining intact ecosystems, but wealthy countries can more easily afford to allocate the necessary space and money. Developed countries also tend to have more established administrative and protective structures for biosphere reserves and other sanctuaries. An increasing number of developing countries are working to establish biosphere reserves, though. A significant incentive, aside from national pride in indigenous species, is the international recognition given to countries with biosphere reserves. Possession of these reserves grants smaller and less wealthy countries some of the same status as that of more powerful countries such as the United States, Germany, and Russia.

Schematic plan of a biosphere reserve. (Beacon Press. Reproduced by permission.)

Some difficult issues surround the biosphere reserve movement. One question that arises is whether reserves are chosen for reasons of biological importance or for economic and political convenience. In many cases national biosphere reserve committees overlook critical forests or endangered habitats because logging and mining companies retain strong influence over national policy makers. Another problem is that in and around many reserves, residents are not yet entirely convinced, with some reason, that management goals mesh with local goals. In theory sustainable development methods and education will continue to encourage communication, but cooperation can take a long time to develop. Among reserve managers themselves, great debate continues over just how much human interference is appropriate, acceptable, or perhaps necessary in a place ideally free of human activity. Despite these logistical and theoretical problems, the idea behind biosphere reserves seems a valid one, and the inclusiveness of biosphere planning, both biological and social, is revolutionary.

Biotechnology

Few developments in science have had the potential for such profound impact on research, technology, and society in general as has biotechnology. Yet authorities do not agree on a single definition of this term. Sometimes, writers have limited the term to techniques used to modify living organisms and, in some instances, the creation of entirely new kinds of organisms.

In most cases, however, a broader, more general definition is used. The Industrial Biotechnology Association, for example, uses the term to refer to any "development of products by a biological process." These products may indeed be organisms or they may be cells, components of cells, or individual and specific **chemicals**. A somewhat more detailed definition is that of the European Federation of Biotechnology, which defines biotechnology as the "integrated use of biochemistry, microbiology, and engineering sciences in order to achieve technological (industrial) application of the capabilities of **microorganisms**, cultured tissue cells, and parts thereof."

By almost any definition, biotechnology has been used by humans for thousands of years, long before modern science existed. Some of the oldest manufacturing processes known to humankind make use of biotechnology. Beer, wine, and breadmaking, for example, all occur because of the process of fermentation. During fermentation, microorganisms such as yeasts, molds, and bacteria are mixed with natural products which they use as food. In the case of wine-making, for example, yeasts live on the sugars found in some type of fruit juice, most commonly, grape juice. They digest those sugars and produce two new products, alcohol and **carbon dioxide**.

The alcoholic beverages produced by this process have been, for better or worse, a mainstay of human civilization for untold centuries. In breadmaking, the products of fermentation are responsible for the wonderful odor (the alcohol) and texture (the **carbon** dioxide) of freshly-baked bread. Cheese and yogurt are two other products formed when microorganisms act on a natural product, in this case milk—changing its color, odor, texture, and taste.

Biotechnology has long been used in a variety of industrial processes also. As early as the seventeenth century, bacteria were used to remove **copper** from its ores. Around 1910, scientists found that bacteria could be used to decompose organic matter in sewage, thus providing a mechanism for dealing efficiently with such materials in **solid waste**. A few years later, a way was found to use microorganisms to produce glycerol synthetically. That technique soon became very important commercially, since glycerol is used in the manufacture of explosives and World War I was about to begin.

Not all forms of biotechnology depend on microorganisms. Hybridization is an example. Farmers long ago learned that they could control the types of animals bred by carefully selecting the parents. In some cases, they actually created entirely new animal forms that do not occur in **nature**. The mule, a hybrid of horse and donkey, is such an animal.

Hybridization has also been used in plant growing for centuries. Farmers found that they could produce food plants with any number of special qualities by carefully selecting the seeds they plant and by controlling growing conditions. As a result of this kind of process, the 2–3-in (5.1–7.6-cm) vegetable known as maize has evolved over the years into the 12-in (30-cm), robust product called corn. Indeed, there is hardly a fruit or vegetable in our diet today that has not been altered by long decades of hybridization.

Until the late nineteenth century, hybridization was largely a trial-and-error process. Then the work of Gregor Mendel started to become known. Mendel's research on the transmission of hereditary characteristics soon gave agriculturists a solid factual basis on which to conduct future experiments in cross-breeding.

Modern principles of hybridization have made possible a greatly expanded use of biotechnology in agriculture and many other areas. One of the greatest successes of the science has been in the development of new food crops that can be grown in a variety of less-than-optimal conditions. The dramatic increase in harvests made possible by these developments has become known as the **agricultural revolution** or green revolution.

Three decades after the green revolution first changed agriculture in many parts of the world, a number of problems with its techniques have become apparent. The agricultural revolution forced a worldwide shift from subsistence farming to cash farming, and many small farmers in developing countries lack the resources to negotiate this shift. A farmer must make significant financial investments in seed, **agricultural chemicals** (fertilizers and pesticides), and machinery to make use of new farming techniques. In developing coun-

tries, peasants do not have and cannot borrow the necessary capital. The seed, chemicals, machinery, and oil to operate the equipment must commonly be imported, adding to already crippling foreign debts. In addition, the new techniques often have harmful effects on the **environment**. In spite of problems such as these, however, the green revolution has clearly made an important contribution to the lessening of world hunger.

Modern methods of hybridization have application in many fields besides agriculture. For example, scientists are now using controlled breeding techniques and other methods from biotechnology to insure the survival of **species** that are threatened or endangered.

The nature of biotechnology has undergone a dramatic change in the last half century. That change has come about with the discovery of the role of **deoxyribosenucleic acid** DNA in living organisms. DNA is a complex molecule that occurs in many different forms. The many forms that DNA can take allow it to store a large amount of information. That information provides cells with the direction they need to carry out all the functions they have to perform in a living organism. It also provides a mechanism by which that information is transmitted efficiently from one generation to the next.

As scientists learned more about the structure of the DNA molecule, they discovered precisely and in chemical terms how genetic information is stored and transmitted. With that knowledge, they have also developed the ability to modify DNA, creating new instructions that direct cells to perform new and unusual functions. The process of DNA modification has come to be known as **genetic engineering**. Since genetic engineering normally involves combining two different DNA molecules, it is also referred to as recombinant DNA research.

There is little doubt that genetic engineering is the best known form of biotechnology today. Indeed, it is easy to confuse the two terms and to speak of one when it is the other that is meant. However, the two terms are different in the respect that genetic engineering is only one type of biotechnology.

In theory, the steps involved in genetic engineering are relatively simple. First, scientists decide what kind of changes they want to make in a specific DNA molecule. They might, in some cases, want to alter a human DNA molecule to correct some error that results in a disease such as diabetes. In other cases, a researcher might want to add instructions to a DNA molecule that it does not normally carry. He or she might, for example, want to include instructions for the manufacture of a chemical such as insulin in the DNA of bacteria that normally lack the ability to make insulin.

Second, scientists find a way to modify existing DNA to correct errors or add new information. Such methods are now well developed. In one approach, enzymes that "recognize" certain specific parts of a DNA molecule are used to cut open the molecule and then insert the new portion.

Third, scientists look for a way to insert the "correct" DNA molecule into the organisms in which it is to function. Once inside the organism, the new DNA molecule may give correct instructions to cells in humans (to avoid genetic disorders), in bacteria (resulting in the production of new chemicals), or in other types of cells for other purposes.

Accomplishing these steps in practice is not always easy. One major problem is to get an altered DNA molecule to express itself in the new host cells. That the molecule is able to enter a cell does not mean that it will begin to operate and function (express itself) as scientists hope and plan. This means that many of the expectations held for genetic engineering may not be realized for many years.

In spite of problems, genetic engineering has already resulted in a number of impressive accomplishments. Dozens of products that were once available only from natural sources and in limited amounts are now manufactured in abundance by genetically engineered microorganisms at relatively low cost. Insulin, human growth hormone, tissue plasminogen activator, and alpha interferon are examples. In addition, the first trials with the alteration of human DNA to cure a genetic disorder were begun in 1991.

The prospects offered by genetic engineering have not been greeted with unanimous enthusiasm by everyone. Many people believe that the hope of curing or avoiding genetic disorders is a positive advance. But they question the wisdom of making genetic changes that are not related to life-threatening disorders. Should such procedures be used for helping short children become taller or for making new kinds of tomatoes? Indeed, there are some critics who oppose *all* forms of genetic engineering, arguing that humans never have the moral right to "play God" with any organism for any reason. As the technology available for genetic engineering continues to improve, debates over the use of these techniques in practical settings are almost certainly going to continue—and to escalate—in the future.

As progress in genetic engineering goes forward, so do other forms of biotechnology. The discovery of monoclonal antibodies is an example. Monoclonal antibodies are cells formed by the combination of tumor cells with animal cells that make one and only one kind of antibody. When these two kinds of cells are fused, they result in a cell that reproduces almost infinitely and that recognizes one and only one kind of antigen. Such cells are extremely valuable in a vast array of medical, biological, and industrial applications, including the diagnosis and treatment of disease, the separation

and purification of proteins, and the monitoring of pregnancy.

Biotechnology became a point of contention in 1992 during planning for the **United Nations Earth Summit** in Rio de Janeiro. In draft versions of the treaty on **biodiversity**, developing nations insisted on provisions that would force biotechnology companies in the developed world to pay fees to developing nations for the use of their genetic resources (the plants and animals growing within their boundaries). Currently, companies have free access to most of these raw materials used in the manufacture of new drugs and crop varieties. President George Bush argued that this provision would place an unfair burden on biotechnology companies in the United States, and he refused to sign the biodiversity treaty that contained this clause. For now, it seems that, for a second time, profits to be reaped from biotechnological advances will elude developing countries. (The Clinton administration subsequently endorsed the provisions of the biodiversity treaty and it was signed by Madeleine Albright, U. S. ambassador to the United Nations, on June 4, 1993.)

Bioterrorism

Bioterrorism refers to the use of lethal biological agents to wage terror against a civilian population. It differs from biological warfare in that it also thrives on public fear, which can demoralize a population. An example of bioterrorism is provided by the **anthrax** outbreak which occurred during September-November 2001 in the United States. Anthrax spores intentionally spread in the mail distribution system caused five deaths and a total of 22 infections. The Centers for Disease Control (CDC) classifies bioterror agents into three categories:

- **Category A Diseases/Agents** that can be easily disseminated or transmitted from person to person and that can result in high **mortality** rates while causing public panic and social disruption. Anthrax, botulism, **plague**, smallpox, tularemis, and viral hemorrhagic fever viruses belong to this category.
- **Category B Diseases/Agents** that are moderately easy to disseminate and that can result in low mortality rates. Brucellosis, food and water safety threats, melioidosis, psittacosis, staphylococcal enterotoxin B, and typhus belong to this category.
- **Category C Diseases/Agents** that include emerging pathogens that could be engineered for mass dissemination in the future because of availability or ease of production and dissemination and that have potential for high mortality rates.

The anthrax attacks of 2001 were very limited in scope compared to the potential damage that could result from large-scale bioterrorism. A large-scale bioterrorism attack on the United States could threaten vital national security interests. Massive civilian casualties, a breakdown in essential services, violation of democratic processes, civil disorder, and a loss of confidence in government could compromise national security, according to a report prepared by four non-profit analytical groups, including the Center for Strategic and International Studies and the John Hopkins Center for Civilian Biodefense Studies.

Probably the first sign of a bioterrorism attack is when people infected during the attack start developing symptoms and showing up in hospital emergency departments, urgent care centers, and doctors' offices. By this time, people infected in the initial attack will have begun spreading it to others.

An added concern is that most physicians have never treated a case of a bioterrorism agent such as smallpox or **Ebola**. This is likely to cause a delay in diagnosis, further promoting the spread of the contagious agent. For example, based on past smallpox history, it is estimated that each person infected during the initial attack will infect another 10–12 persons. In the case of smallpox, only a few **virus** particles are needed to cause infection. One ounce of the smallpox virus could infect 3,000 persons if distributed through an **aerosol** attack, according to William Patrick, senior scientist in the United States biological weapons program before its official termination in 1969, in a 2001 *Washington Post Magazine* interview. Given these numbers, a terrorist with enough smallpox virus to fill a soda can could potentially infect 36,000 people in the initial attack who could then infect another 360,000–432,000. Of these, an estimated 30% or 118,800–140,400, would likely die.

Using disease as a weapon is not a new idea. It goes back at least hundreds of years and possibly much further back. One account of the beginning of the great plague epidemic which occurred in Europe in the fourteenth century and killed a third of the population states that it started with an act of bioterrorism, as reported by A. Daniels in National

Review. The Tartars were attacking a Genoan trading post on the Crimean coast in 1346 when the plague broke out among them. Turning the situation into a weapon, the Tartars catapulted the dead and diseased bodies over the trading post walls. The Genoans soon developed the deadly disease and took it back with them to Genoa, where it soon engulfed all of Europe. Another example from early North American history is provided by the British soldiers who gave smallpox-infected blankets to Native Americans in the 1700s.

The Hague Conventions of 1899 and 1907 included clauses outlawing the deliberate spread of a deadly disease. However, during World War I, German soldiers attempted to infect sheep destined for Russia with anthrax. After the war, 40 members of the League of Nations, the precursor of the United Nations, outlawed biological weapons. But many countries continued biological warfare research. During World War II, the Japanese mass-produced a number of deadly biological agents, including anthrax, typhoid, and plague. They infected water supplies in China with typhoid, killing thousands, including 1,700 Japanese soldiers. Bioterrorism entered popular literature more than a century ago when science fiction writer H. G. Wells wrote "The Stolen Bacillus,", a novel in which a terrorist tries to infect the London water supply with **cholera**, an acute and often deadly disease.

Throughout the Cold War era, several nations, including the United States and Soviet Union, developed sophisticated facilities to produce large amounts of biological agents to be used as weapons. Most nations have renounced the manufacture, possession, or use of biological weapons. However, a few rogue nations, including Iran, Iraq, and North Korea, still have active biological warfare programs according to the United States military. Many experts in the field believe that terrorists could obtain deadly biological agents from these rogue nations, or from other terrorist or criminal groups active in nations of the former Soviet Union.

Among the **Category A Diseases/Agents**, six highly lethal biological agents are most likely to be used by terrorists, according to the CDC. Depending on the biological agent, disease could be spread through the air, or by contaminating the food or water supply.

- Anthrax, caused by *Bacillus anthracis*, is an acute infectious disease that most commonly occurs in hoofed animals but can also infect humans. Initial symptoms are flu-like and can occur up to several weeks after exposure. Treatment with antibiotics after exposure but before symptoms develop is usually successful in preventing infection. There is a anthrax vaccine used by the military but it is not available for civilian use. About 90% of people who are infected die.
- Botulism is a muscle-paralyzing disease caused by a toxin produced by a bacterium called *Clostridium botulinum*. The botulinum toxin is the single most poisonous substance known, according to the Center for Civilian Biodefense Strategies. It is a major bioterrorism threat because of its extreme potency and high rate of death after exposure. It is not contagious and would likely be used by terrorists to contaminate food or water supplies. Flu-like symptoms, along with difficulty speaking, seeing, or swallowing, usually occur 12–72 hours after exposure.
- Plague is a disease caused by *Yersinia pestis*, a bacterium found in rodents and their fleas in many areas around the world. When released into the air, the bacterium can survive for up to an hour. Of the three types of plague (pneumonic, bubonic, and septicemic), pneumonic is the one most likely to be used by terrorists since large stockpiles were developed by the United States and Soviet Union in the 1950s and 1960s. Symptoms include fever, headache, weakness, chest pain, and cough. Early treatment with antibiotics can reduce the risk of death.
- Smallpox is caused by the *variola major* virus and was eliminated from the world in 1977. However, the Soviet Union had large stockpiles of the virus in the 1980s and much of it may still be stored in the former Soviet republics and available to terrorists. Smallpox spreads directly from person to person and can be dispersed in the air. Also, the amount needed to cause infection is very small. Symptoms, including high fever, fatigue, and head and back aches, commonly develop in about 12 days. Flat, red skin lesions follow initial symptoms. Death occurs in about 30% of the cases. There is a vaccine against smallpox but routine vaccinations ended in 1972. The government has an emergency supply of about 15 million doses of the vaccine.
- Tularemia, an infectious disease caused by the bacterium *Francisella tularensis,*, is usually found in animals but can also infect humans. It could be delivered in a terrorist attack through food, water, or air. Symptoms of tularemia include sudden fever, chills, headache, muscle ache, dry cough, weakness, and pneumonia. The disease can be treated with antibiotics if started early. As of May 2002, the U.S. **Food and Drug Administration** (FDA) was reviewing a possible vaccine for the disease.
- Exotic diseases, including viral hemorrhagic fevers, such as Ebola, and arenaviruses, such as the one causing Lassa fever, are also biological agents of interest to terrorists. The Ebola virus is one of the most lethal known, and easily spreads from person to person, with no vaccine or effective treatment presently known.

The possibility that bioterrorists may strike at food and water supplies is of serious concern to health and environmental officials. Such an attack initially could be perceived as unintentional food **poisoning**, which might delay recognition of the outbreak, and complicate identification of the contaminated food. What many consider an act of

bioterrorism by domestic terrorists occurred in The Dalles, Oregon, in 1984. Members of a religious cult contaminated restaurant salad bars with *Salmonella typhimurium*, a non-lethal bacterium that nonetheless infected 751 people. The incident was reportedly a trial run for a more extensive attack to disrupt local elections later that year.

"The United States food supply is increasingly characterized by centralized production and wide distribution of products," according to a May 2002 article in *The Lancet*, the "Deliberate contamination of a commercial food product could cause an outbreak of disease, with many illnesses dispersed over wide geographical areas.". The article also stated that the anthrax letter attacks of 2001 have shown that even a small biological attack can produce considerable public nervousness and challenge the health care system.

Biotic community

All the living organisms sharing a common **environment**. The members of a biotic community are usually divided into three major categories: producers, consumers, and **decomposers**, based on the organisms' nutritional habits. Producers (sometimes called autotrophs) include plants and some forms of bacteria that use solar or chemical energy to convert simple compounds into their food. Consumers (sometimes called heterotrophs) obtain the energy they need by eating living plants and animals, or dead plant and animal material (**detritus**). Primary consumers (herbivores) eat plants, while secondary consumers (carnivores) eat other consumers. Consumers that feed on dead plant and animal material are called detrivores. There are two classes of detrivores: detritus feeders and decomposers. Detritus feeders (e.g., crabs, termites, earthworms, vultures) consume dead organisms or organic wastes, while decomposers (**fungi** and bacteria) feed on dead plant material, converting it into simple inorganic compounds such as **carbon dioxide**, water, and ammonia. Decomposers are also an important food sources for other consumers (e.g., worms and insects) living in the **soil** or water.

Biotic impoverishment

see **Biodiversity**

Biotoxins

The term biotoxin refers to naturally occurring, poisonous agents that can cause illness or injury to humans, animals, and marine life. They may come from bacteria, **fungi**, algae, or virii.

Some of the more well-known bacterial biotoxins include *Bacillus anthracis* (**anthrax**), *Brucella melitensis* and *Brucella suis* (brucellosis), *Vibro cholerae* (**cholera**), and *Yersinia pestis* (**plague**).

Diseases spread by viral biotoxins include encephalomyelitis, viral hemorrhagic fever (yellow fever, ebola-marburg, dengue fever), and variola major (smallpox).

Biotoxins may be distributed through wind-borne spores or through contaminated food or water. Some biological agents have also been aerosolized or deliberately introduced into food and water supplies for use as bioweapons.

Marine biotoxins are often responsible for large-scale **fish kills** and can cause severe illness in humans who consume tainted fish or shellfish. Symptoms of shellfish **poisoning** include diarrhea, stomach cramps, headache, nausea, vomiting, and in extreme cases neurotoxic effects including paralysis, seizures, and death. Common marine biotoxins

include ciguatera fish poisoning (CFP) toxin and domoic **acid**. Harmful algae blooms (HAB) are sometimes called red tides or brown tides. Some HABs, such as *Pfiesteria piscicida*, can be sources of marine biotoxins that potentially harm marine life and humans.

Bioventing

The process for treating environmental contaminants in the soils located between the ground surface and the **water table** by inducing **aerobic** biodegradation. Air is introduced into the contaminated soils, providing oxygen for native **soil** bacteria to use in the biodegradation of organic compounds. The process is typically accomplished by extracting and/or injecting air from trenches or shallow **wells** which are screened within the unsaturated soils. The systems are similar to those used in vapor extraction. The main difference is that air extraction rates are low to minimize physical removal (stripping) of volatile organic compounds (VOCs) reducing the need for expensive treatment of the off-gases. The process may include the addition of nutrients such as common fertilizers, to provide **nitrogen** and phosphate for the bacteria. Bioventing is particularly attractive around buildings and actively used areas because it is relatively nonintrusive and results in minimal disturbance during installation and operation. The process is most suitable for **petroleum** hydrocarbon blends such as **gasoline**, jet fuel, and diesel oil, for petroleum distillates such as **toluene**, and for nonchlorinated solvents. *See also* Biodegradable; Bioremediation; Vapor recovery system

BirdLife International

"From research...to action. From birds...to people." So reads the cover of the BirdLife International's annual report. This statement perfectly describes the beliefs of BirdLife International, a group founded under the original name International Council for Bird Preservation in 1922 by well-known American and European bird enthusiasts for the **conservation** of birds and their habitats.

Under the leadership of Director and Chief Executive Dr. Michael Rands, the group works to protect endangered birds worldwide and to promote public awareness of their ecological importance. BirdLife International has grown from humble beginnings in England to a federation of over 300 member organizations representing approximately 2.2 million people in 103 countries and territories. This includes developing tropical countries where few, if any, conservation movements existed prior to BirdLife International. There is also a worldwide network of enthusiastic volunteers.

BirdLife International is a key group in international efforts to protect bird **migration** routes, and also works to educate the public about **endangered species** and their ecological importance. The BirdLife International gathers and disseminates information about birds, maintaining a computerized data bank from which it generates reports. It conducts periodic symposiums on bird-related issues, runs the World Bird Club, maintains a Conservation Fund, runs special campaigns when opportunities such as the Migratory Bird Campaign present themselves, and develops and carries out priority projects in their Conservation Program.

The BirdLife International Conservation Program has undertaken many projects on behalf of endangered birds. In 1975, BirdLife International began a captive breeding program for the pink pigeon (*Nesoenas mayeri*), a native of the island of Mauritius in the Indian Ocean, because the total population of this **species** had dwindled to less than 20 birds. As a result of these efforts, well over 100 of the birds were successfully raised in captivity. Later, several pairs were released at Mauritius' Botanic Gardens of Pamplemousses. BirdLife International has focused on other seriously endangered birds as well, such as the imperial parrot (*Amazona imperialis*). In an attempt to protect its threatened **habitat**, BirdLife International has helped buy a forest reserve in Dominica, where only 60 of the **parrots** still survive. With the help of local citizens and educational facilities, BirdLife International hopes that their efforts to save the imperial parrot will be as successful as their work with pink pigeons.

Another important BirdLife International project is the group's work to save the red-tailed parrot (*Amazona brasiliensis*) of southeastern Brazil. This project involves support of an extensive plan to convert an entire nearby island

into a refuge for the parrots, which exist in only a very few isolated parts of Brazil. BirdLife International has also focused on islands in other conservation projects. The council purchased Cousin Island (famous for its numerous seabirds), in an effort to save the Seychelles brush warbler (*Acrocephalus sechellensis*). Native only to Cousin Island, this entire brush warbler species numbered only 30 individuals before BirdLife International bought their island. Today, there are more than 300 bush warblers, and BirdLife International continues to be actively involved in helping to breed more.

BirdLife International's publications are many and varied. Quarterly, it issues *Bird Conservation International*, *U.S. Birdwatch*, and *World Birdwatch* newsletter; and periodically, it issues *Bustard Studies*. It also publishes the well-respected series *Bird Red Data Books*, and such monographs as *Important Bird Areas in Europe* and *Key Forests for Threatened Birds in Africa*. BirdLife International produces numerous technical publications and study reports, and, occasionally, Conservation Red Alert pamphlets on severely threatened birds.

Birth control

see **Family planning; Male contraceptives**

Birth defects

Birth defects, also known as congenital malformations, are structural or metabolic abnormalities present at birth. While subtle variations from the normal, of no clinical interest, occur in about half of all individuals in the United States, significant congenital defects are found in about 3% of live births. Fortunately, only about half of these require medical attention.

Birth defects may result from genetic causes or environmental insult. Defective genes are not easily repaired and thus are perhaps less interesting than teratogenic substances to environmentalists. It is theoretically possible to limit exposure to teratogens by elimination of the agent in the **environment** or by modification of behavior to prevent contact. It should be noted, however, that the causes of more than half of congenital malformations remain unknown.

Birth defects of genetic origin may be due to aberrant chromosome number or structure, or to a single gene defect. Normal humans have 46 chromosomes, and variation from this number is referred to as aneuploidy. Down's syndrome, an example of aneuploidy, is usually characterized by an extra chromosome designated number 21. The Down's individual thus has a total of 47 chromosomes, and the presence of the extra chromosome results in multiple defects. These include mental retardation and physical characteristics comprising a small round head, eyes that slant slightly upward, a large and frequently protruding tongue, low set ears, broad hands with short fingers and short stature. People with Down's syndrome are particularly vulnerable to **leukemia**. Children with this condition are rarely born to mothers less than 25 years of age (less than one in 1,500), but the prevalence of Down's syndrome babies increases with mothers older than 45 (about one in 25). Down's syndrome can be detected during pregnancy by chromosome analysis of fetal cells. Fetal chromosomes may be studied by chorionic villus sampling or by amniocentesis.

Other congenital abnormalities with a chromosomal basis include Klinefelter's syndrome, a condition of male infertility associated with an extra X chromosome, and Turner's syndrome, a condition wherein females fail to mature sexually and are characterized by the aneuploid condition of a missing X chromosome. Achondroplasia is a birth defect due to a dominant **mutation** of a Mendelian gene that results in dwarfism. Leg and arm bones are short but, the trunk is normal and the head may be large. Spontaneous mutation accounts for most achondroplasia. The **mortality** rate for affected individuals is so high that the gene would be lost if it were not for mutation. Albinism, a lack of pigment in the skin, eyes, and hair, is another congenital defect caused by a single gene, which in this case is recessive.

The developing fetus is at risk for agents which can pass the placental barrier such as infectious **microbes**, drugs and other **chemicals**, and **ionizing radiation**. Transplacental teratogens exert their effect on incompletely formed embryos or fetuses during the first three months of pregnancy. Organs and tissues in older and full term fetuses appear much as they will throughout life. It is not possible to alter the development of a fully formed structure. However, prior to the appearance of an organ or tissue, or during the development of that structure, teratogenic agents may have a profoundly deleterious effect.

Perhaps the best known **teratogen** is the sedative thalidomide which induces devastating anatomical abnormalities. The limb bones are either shortened or entirely lacking leading to a condition known as phocomelia. Intellectual development of thalidomide babies is unaffected. The experience with this drug, which started in 1959 and ended when it was withdrawn in 1961, emphasizes the fact that medications given to pregnant mothers generally cross the placenta and reach the developing embryo or fetus. Another

drug that effects developmental abnormalities is warfarin which is used in anticoagulant therapy. It can cause fetal hemorrhage, mental retardation, and a multiplicity of defects to the eyes and hands when given to pregnant women.

The teratogenic effects of alcohol, or the life style that may accompany alcohol abuse, serve to illustrate that the term environment includes not only air and water but the personal environment as well. Alcoholism during pregnancy can result in "fetal alcohol syndrome" with facial, limb, and heart defects accompanied by growth retardation and reduced intelligence. The effects of alcohol may be magnified by factors associated with alcoholism such as poor diet, altered **metabolism** and inadequate medical care. Because neither the time of vulnerability nor the toxic level of alcohol is known, the best advice is to eschew alcohol as a dietary constituent altogether during pregnancy.

Disease of the mother during pregnancy can present an environmental hazard to the developing fetus. An example of such a hazard is the viral disease German measles, also known as rubella. The disease is characterized by a slight increase in temperature, sore throat, lethargy and a rash of short duration. Greatest hazard to the fetus is during the second and third month. Children born of mothers who had rubella during this period may exhibit cataracts, heart defects, hearing loss and mental retardation. Obviously, the **virus** transverses the placenta to infect the embryo or fetus and that infection may persist in the newborn. Birth defects associated with rubella infection have decreased since the introduction of a rubella vaccine.

The most common viral infection that occurs in human fetuses is that of a herpes virus known as cytomegalovirus. The infection is detected in about 1–2% of all live births. Most newborns, fortunately, do not manifest symptoms of the infection. However, for a very small minority, the effects of congenital cytomegalovirus are cruel and implacable. They include premature birth or growth retardation prior to birth, frequently accompanied by hepatitis, enlarged spleen, and reduction in thrombocytes (blood cells important for clotting). Abnormally small heads, mental retardation, cerebral palsy, heart and cerebral infection, bleeding problems, hearing loss and blindness occur. Exposure of the fetus to the virus occurs during infection of the pregnant woman or possibly from the father, since cytomegalovirus has been isolated from human semen.

Other infections known to provoke congenital defects include herpes simplex virus type II, toxoplasmosis, and syphilis.

Methylmercury is an effective **fungicide** for seed grain. Accidental human consumption of food made from treated seeds has occurred. Industrial **pollution** of sea water with organic **mercury** resulted in the contamination of fish, consumed by humans, from Minamata Bay in Japan. It has been established that organic mercury passes the placental barrier with effects that include mental retardation and a cerebral palsy-like condition due to brain damage. Anatomical birth defects, engendered by organic mercury, include abnormal palates, fingers, eyes and hearts. The toxicity of methylmercury affects both early embryos and developing fetuses. Exclusion of mercury from human food can be effected by not using organic mercury as a fungicide and by ending industrial **discharge** of mercury into the environment.

Of course other chemicals may be hazardous to the offspring of pregnant women. Polychlorinated biphenyl (PCB)s, relatively ubiquitous but low level oily contaminants of the environment, cause peculiar skin pigmentation, low birth weights, abnormal skin and nails, and other defects in offspring when accidentally ingested by pregnant woman.

Uncharacterized mixtures of toxic chemicals which contaminate the environment, are thought to be potential teratogens. Cytogenetic (chromosomal) abnormalities and increased birth defects were detected among the residents of **Love Canal**, New York. **Cigarette smoke** is the most common mixture of **toxic substance** to which fetuses are exposed. **Tobacco smoke** is associated with reduced birth weight but not specific birth anatomical abnormalities.

Much concern has arisen over the damaging effects of ionizing radiation, particularly regarding diagnostic x-rays and **radiation exposure** from nuclear accidents. The latter concern was given international attention following the explosion at the Ukraine's **Chernobyl Nuclear Power Station** in 1986. Fear that birth defects would occur as a result was fueled by reports of defects in Japanese children whose mothers were exposed to radiation at Hiroshima. Scientists believe that radiation to the fetus can result in many defects including various malformations, mental retardation, reduced growth rate and increased risk for leukemia. Fortunately, however, the risk of these effects is exceptionally low. Fetal abnormalities caused by factors other than radiation are thought to be about 10 times greater than those attributed to radiation during early pregnancy. However small the risk, most women choose to limit or avoid exposure to radiation during early pregnancy. This may be part of the reason for the increased popularity of diagnostic ultrasound as opposed to x ray.

While concern is expressed for particular teratogenic agents or procedures, the etiology of most birth defects is unknown. Common defects, with unknown etiology, include hare lip and cleft palate, extra fingers and toes, fused fingers, extra nipples, various defects in the heart and great vessels, cerebral palsy (sometimes as a result of difficult labor and delivery but frequently for no known cause), narrowing of the entrance to the stomach, esophageal abnormalities, spina bifida, clubfoot, hip defects, and many, many others. Since the majority of birth defects are not caused by known effects

of disease, drugs, chemicals or radiation, much remains to be learned.

Bison

The American bison (*Bison bison*) or "buffalo" is one of the most famous animals of the American West. Providing food and hides to the early Indians, it was almost completely eliminated by hunters, and now only remnant populations exist though its future survival seems assured.

Scientists do not consider the American bison a true buffalo (like the Asian water buffalo or the African buffalo), since it has a large head and neck, a hump at the shoulder, and 14 pairs of ribs instead of 13. In America, however, the names are used interchangeably. A full-grown American bison bull stand 5.5–6 ft (1.7–1.8 m) at the shoulder, extends 10–12.25 ft (3–3.8 m) in length from nose to tail, and weighs 1,600–3,000 lb (726–1,400 kg). Cows usually weigh about 900 lb (420 kg) or less. Bison are brown-black with long hair which covers their heads, necks, and humps, forming a "beard" at the chin and throat. Their horns can have a spread as large as 35 in (89 cm). Bison can live for 30 or more years, and they are social creatures, living together in herds. Bison bulls are extremely powerful; a charging bull has been known to shatter wooden blanks 2 in (5 cm) thick and 12 in (30 cm) wide.

The American bison is one of the most abundant animals ever to have existed on the North American continent, roaming in huge herds between the Appalachians and the Rockies as far south as Florida. One herd seen in Arkansas in 1870 was described as stretching "from six to 10 mi (9.7 to 16.1 km) in almost every direction." In the far West, the herds were even larger, stretching as far as the eye could see, and in 1871 a cavalry troop rode for six days through a herd of bison.

The arrival of Europeans in America sealed the fate of the American bison. By the 1850s massive slaughters of these creatures had eliminated them from Illinois, Indiana, Kentucky, Ohio, New York, and Tennessee. After the end of the Civil War in 1865, railroads began to bring a massive influx of settlers to the West and bison were killed in enormous numbers. The famous hunter "Buffalo Bill" Cody was able to bag 4,280 bison in just 18 months, and between 1854 and 1856, an Englishman named Sir George Gore killed about 6,000 bison along the lower Yellowstone River. Shooting bison from train windows became a popular **recreation** during the long trip west; there were contests to see who could kill the most animals on a single trip, and on one such excursion a group accompanying Grand Duke Alexis of Russia shot 1,500 bison in just two days. When buffalo tongue became a delicacy sought after by gourmets in the east, even more bison were killed for their tongues and their carcasses left to rot.

In the 1860s and 1870s extermination of the American bison became the official policy of the United States Government in order to deprive the Plains Indians of their major source of food, clothing, and shelter. During the 1870s, two to four million bison were shot each year, and 200,000 hides were sold in St. Louis in a single day. Inevitably, the extermination of the bison helped to eliminate not only the Plains Indians, but also the predatory animals dependent on it for food, such as plains **wolves**. By 1883, according to some reports, only one wild herd of bison remained in the West, consisting of about 10,000 individuals confined to a small part of North Dakota. In September of that year, a group of hunters set off to kill the remaining animals and by November the job was done.

By 1889 or 1890 the entire North American bison population had plummeted to about 500 animals, most of which were in captivity. A group of about 20 wild bison remained in **Yellowstone National Park**, and about 300 wood bison (*Bison bison athabascae*) survived near Great Slave Lake in Canada's Northwest Territories. At that time, naturalist William Temple Hornaday led a campaign to save the **species** from complete **extinction** by the passage of laws and other protective measures. Canada enacted legislation to protect its remnant bison population in 1893 and the United States took similar action the following year.

Today, thousands of bison are found in several national parks, private ranches, and **game preserves** in the United States. About 15,000 are estimated to inhabit Wood Bison **National Park** and other locations in Canada. The few hundred wood bison originally saved around Great Slave Lake also continued to increase in numbers until the population reached around 2,000 in 1922. But in the following years, the introduction of plains bison to the area caused hybridization, and pure specimens of wood bison probably disappeared around Great Slave Lake. Fortunately, a small, previously unknown herd of wood bison was discovered in 1957 on the upper North Yarling River, buffered from hybridization by 75 mi (121 km) of swampland. From this herd (estimated at about 100 animals in 1965) about 24 animals were successfully transplanted to an area near Fort Providence in the Northwest Territories and 45 were relo-

cated to Elk Island National Park in Alberta. Despite these rebuilding programs, the wood bison is still considered endangered, and is listed as such by the U. S. Department of the Interior. It is also listed in Appendix I of the Convention on International Trade in **Endangered Species** of Fauna and Flora (CITES) treaty.

Controversy still surrounds the largest herd of American bison (5,000–6,000 animals in the early 1990s) in Yellowstone National Park. The free-roaming bison often leave the park in search of food in the winter and Montana cattle ranchers along the park borders fear that the bison could infect their herds with brucellosis, a contagious disease that can cause miscarriages and infertility in cows. In an effort to prevent any chance of brucellosis transmission, the **National Park Service** (NPS) and the Montana Department of Fish, **Wildlife** and Parks, along with sport hunters acting in cooperation with these agencies, killed 1,044 bison between 1984 and 1992. Montana held a lottery-type hunt, and 569 bison were killed in the winter of 1988–89, and 271 were killed in the winter of 1991–92. The winter of 1996–97 was exceptionally harsh, and some 850 buffalo of the Park's remaining 3,500 starved or froze to death. In addition, the NPS, the **U.S. Department of Agriculture** (USDA), and the Montana Department of Livestock cooperated in a stepped-up buffalo killing program, in which some 1,080 were shot or shipped off to slaughterhouses. In all, more than half of Yellowstone's bison herd perished that winter.

Wildlife protection groups, such as the **Humane Society of the United States** and the **Fund for Animals**, have protested the **hunting** of these bison—which usually consists of walking up to an animal and shooting it. Animal protection organizations have offered alternatives to the killing of the bison, including fencing certain areas to prevent them from coming into contact with cattle. Conversely, Montana state officials and ranchers, as well as the USDA, have long pressured the National Park Service to eradicate many or all of the Yellowstone bison herd or at least test the animals and eliminate those showing signs of brucellosis. Such an action, however, would mean the eradication of most of the Yellowstone herd, even though no bison have not been known to infect a single local cow.

There is also a species of European bison called the wisent (*Bison bonasus*) which was once found throughout much of Europe. It was nearly exterminated in the early 1900s, but today a herd of about 1,600 animals can be found in a forest on the border between Poland and Russia. The European bison is considered vulnerable by **IUCN—The World Conservation Union**. *See also* Endangered Species Act; Endangered species; Overhunting; Rare species; Wildlife management

Black lung disease

Black lung disease, also known as anthracosis or **coal** workers' pneumoconiosis, is a chronic, fibrotic lung disease of coal miners. It is caused by inhaling coal dust which accumulates in the lungs, and forms black bumps or coal macules on the bronchioles. These black bumps in the lungs give the disease its common name. Lung disease among coal miners was first described by German mineralogist Georgius Agricola in the sixteenth century and it is now a widely recognized occupational illness.

Black lung disease occurs most often among miners of anthracite (hard) coal, but it is found among soft coal miners and graphite workers as well. The disease is characterized by gradual onset—the first symptoms usually appear only after 10–20 years of exposure to coal dust. The extent and severity of the disease is clearly related to the length of this exposure. The disease also appears to be aggravated by

cigarette smoking. The more advanced forms of black lung disease are frequently associated with **emphysema** or chronic **bronchitis**. There is no real treatment for this disease, but it may be controlled or its development arrested by avoiding exposure to coal dust. Black lung disease is probably the best know occupational illness in the United States. In some regions, more than 50% of coal miners develop the disease after 30 or more years on the job. *See also* Fibrosis; Respiratory diseases

Black-footed ferret (*Mustela nigripes*). (Visuals Unlimited. Reproduced by permission.)

Black-footed ferret

A member of the Mustelidae (weasel) family, the black-footed ferret (*Mustela nigripes*) is the only ferret native to North America. It has pale yellow fur, an off-white throat and belly, a dark face, black feet, and a black tail. The black-footed ferret usually grows to a length of 18 in (46 cm) and weighs 1.5–3 lb (0.68–1.4 kg), though the males are larger than the females. These ferrets have short legs and slender bodies, and lope along by placing both front feet on the ground followed by both back feet.

Ferrets live in prairie dog burrows and feed primarily upon **prairie dogs**, mice, squirrels, and gophers, as well as small rabbits and carrion. Ferrets are nocturnal animals; activity outside the burrow occurs after sunset until about two hours before sunrise. They do not hibernate and remain active all year long.

Breeding takes place once a year, in March or early April, and during the mating season males and females share common burrows. The gestation period lasts approximately six weeks, and the female may have from one to five kits per litter. The adult male does not participate in raising the young. The kits remain in the burrow where they are protected and nursed by their mother until about four weeks of age, usually sometime in July, when she weans them and begins to take them above ground. She either kills a prairie dog and carries it to her kits or moves them into the burrow with the dead animal. During July and early August, she usually relocates her young to new burrows every three or four days, whimpering to encourage them to follow her or dragging them by the nape of their neck. At about eight weeks old the kits begin to play above ground. In late August and early September the mother positions her young in separate burrows, and by mid-September her offspring have left to establish their own territories.

Black-footed ferrets, like other members of the mustelid family, establish their territories by scent marking. They have well developed lateral and anal scent glands. The ferrets mark their territory by either wiggling back and forth while pressing their pelvic scent glands against the ground, or by rubbing their lateral scent glands against shrubs and rocks. Urination is a third form of scent marking. Males establish large territories that may encompass one or more females of the **species** and exclude all other males. Females establish smaller territories.

Historically, the black-footed ferret was found from Alberta, Canada southward throughout the Great Plains states. The decline of this species began in the 1800s with the settling of the west. Homesteaders moving into the Great Plains converted the prairie into agricultural lands, which led to a decline in the population of prairie dogs. Considering them a nuisance species, ranchers and farmers undertook a campaign to eradicate the prairie dog. The black-footed ferret is dependent upon the prairie dog: it takes 100–150 acres (40–61 ha) of prairie-dog colonies to sustain one adult. Because it takes such a large area to sustain a single adult, one small breeding group of ferrets requires at least 10 mi^2 (26 km^2) of **habitat**. As the prairie dog colonies became scattered, the groups were unable to sustain themselves.

In 1954 the **National Park Service** began capturing black-footed ferrets in an attempt to save them from their endangered status. These animals were released in **wildlife** sanctuaries that had large prairie dog populations. Black-footed ferrets, however, are highly susceptible to canine distemper, and this disease wiped out the animals the park service had relocated.

In September 1981, scientists located the only known wild population of black-footed ferrets near the town of

Meeteetse in northwestern Wyoming. The colony lived in 25 prairie dog towns covering 53 mi^2 (137 km^2). But in 1985 canine distemper decimated the prairie dog towns around Meeteetse and spread among the ferret population, quickly reducing their numbers. Researchers feared that without immediate action the black-footed ferret would become extinct. The only course of action appeared to be removing them from the wild. If an animal had not been exposed to canine distemper, it could be vaccinated and saved. Some animals from the Meeteetse population did survive in captivity.

There is a breeding program and research facility called the National Black-footed Ferret Conservation Center in Wyoming, and in 1987 the Wyoming Fish and Game Department implemented a plan for preserving the black-footed ferret within the state. Researchers identified habitats where animals bred in captivity could be relocated. The program began with the 18 animals from the wild population located at Meeteetse. In 1987 seven kits were born to this group. The following year 13 female black-footed ferrets had litters and 34 of the kits survived. In 1998 about 330 kits survived. Captive propagation efforts have improved the outlook for the black-footed ferret, and captive populations will continue to be used to reestablish ferrets in the wild. Almost 2,000 black-footed ferrets that were bred and raised in captivity have been released into the wild.

Blackout/brownout

A blackout is a total loss of electrical power. A blackout is usually defined as a drop in line voltage below 80 volts (V) (the normal voltage is 120V), since most electrical equipment will not operate below these levels. A blackout may be due to a planned interruption, such as limiting of loads during power shortages by rotating power shutoffs through different areas, or due to an accidental failure caused by human error, a failure of generating or transmission equipment, or a storm. Blackouts can cause losses of industrial production, disturbances to commercial activities, traffic and **transportation** difficulties, disruption of municipal services, and personal inconveniences. In the summer of 1977, a blackout caused by transmission line losses during a storm affected the New York City area. About nine million people were affected by the blackout, with some areas without power for more than 24 hours. The blackout was accompanied by looting and vandalism. A blackout in northeastern United States and eastern Canada due to a switching relay failure in November of 1965 affected 30 million people and resulted in improved electric utility power system design.

A brownout is a condition (usually temporary, but which may last longer, i.e., from periods ranging from fractions of a second to hours) when the alternating current (AC) electrical utility voltage is lower than normal. If the brownout lasts less than a second, it is called a *sag*. Brownouts may be caused by overloaded circuits, but are sometimes caused intentionally by a utility company in order to reduce the amount of power drawn by users during peak demand periods, or unintentionally when demand for electricity exceeds generating capacity. A sag can also occur when line switching is employed to access power from secondary utility sources. Equipment such as shop tools, compressors, and elevators starting up on a shared power line can cause a sag, which can adversely affect other sensitive electronic equipment such as computers. Generally, electrical utility customers do not notice a brownout except when it does affect sensitive electronic equipment.

Measures to protect against effects of blackouts and brownouts include efficient design of power networks, interconnection of power networks to improve **stability**, monitoring of generating reserve needs during periods of peak demand, and standby power for emergency needs. An individual piece of equipment can be protected from blackouts and brownouts by the use of an uninterruptible power source (UPS). A UPS is a device with internal batteries that is used to guarantee that continuous power is supplied to equipment even if the power supply stops providing power or during line sags. Commonly the UPS will boost voltage if the voltage drops to less than 103V and will switch to battery power at 90V and below. Some UPS devices are capable of shutting down the equipment during extended blackouts.

Blow-out

A blow-out occurs where the **soil** is left unprotected to the erosive force of the wind. Blow-outs commonly occur as depressional areas, once enough soil has been removed. They most often occur in sandy soils, where vegetation is sparse.

Blue Angel

The best known environmental product certification effort outside the United States, the Blue Angel program was initiated by the German government in 1977. The Blue Angel label features a stylized angel with arms outstretched encircled by a laurel wreath. Since its inception, the program has certified more than 4,000 products, including automobiles, batteries, and deodorants, as environmentally safe. Similar, government-sponsored certification programs also exist in Canada (Environmental Choice) and Japan (Ecomark). *See also* Environmental advertising and marketing; Green Cross; Green Seal

Blue revolution (fish farming)

The blue revolution has been brought about in part by a trend towards more healthy eating which has increased the consumption of fish. Additionally, the supply of wild fish is declining, and some **species**, such as cod, striped sea bass, **salmon**, haddock, and flounder, have already been overfished. **Aquaculture**, or fish farming, appears to be a solution to the problems created by the law of supply and demand. Farm-raised fish currently account for about 15% of the market. There are 93 species of fin fish, seven species of shrimp, and six species of crawfish, along with numerous species of clams, oysters and shellfish that are currently being farm raised worldwide.

There are five central components to all fish farming operations: fish, water supply, nutrition, management and a contained method. Ideally, every aspect of the fishes' **environment** is scientifically controlled by the farmer. The quality of the water should be constantly monitored and adjusted for **pH** and numerous other factors, including oxygen content. Adequate water circulation is also necessary to insure that waste matter does not accumulate in the cages, for this can lead to outbreaks of disease. The fish are fed formulated diets that contain only enough protein for optimal growth. They are fed regulated amounts that vary according to stage of development, water temperature, and the availability of naturally occurring food in their **habitat**.

Herbicides are used on a regular basis to control any unwanted aquatic vegetation and to prevent fouling of cages. Vaccines are routinely given to the fish to prevent disease, although their effectiveness against most pathogens has yet to be determined. Antibiotics are routinely placed in the food that is fed to farm raised fish, a practice which many have questioned. When given over a prolonged period of time, antibiotics can result in higher incidences of disease because bacterial strains develop **resistance** to them.

Fish that are raised on farms mature in rearing units that are frequently located on shore. These on shore units are typically ponds, large circular tanks or concrete enclosures. Many types of freshwater fin fish are raised in pond systems. Ponds that are easy to harvest, drain and refill are the most economical. Walleye, perch and northern pike are a few of the cool-water species that are raised in pond cultures. Warm-water species such as catfish, carp, and tilapia are also common. A few cold water species, especially trout and salmon, can also be raised in pond systems. Most pond systems are **monoculture** in **nature**, so only one type of fish is raised in each pond.

Silos, raceways, and circular pools are commonly used in fish farming. These are popular because they require a small land base in comparison with most other systems. Trout and salmonoid species are frequently raised in raceways, which are rectangular enclosures usually made of cement, fiberglass or metal, and positioned in a series so that water flows from one into the next. Circular pools are shallow with a center drain. They are easy to clean and maintain, since the growth of aquatic vegetation is usually minimal. Silos are very deep, circular tanks that are similar to silos used for grain storage on traditional farms.

All on shore fish farming operations use large quantities of water, and their operations are either open or closed systems. In open systems the water is used only once, flowing into a pool or through a series of pools before being discharged into a **drainage** ditch, creek, or river. Open systems are used whenever possible because they are relatively inexpensive. In most cases, farmers are not required to treat the water before it is discharged, which poses an environmental hazard because the organic fish wastes, the residues of medications, and the herbicides used in the operation enter the water supply unchecked.

Closed systems are not popular among fish farmers because they are very expensive to build, maintain and oper-

ate. In a closed system used water is treated and then reused in the farming operation. The treatment process can include disinfection, removal of organic wastes that have dissolved in the water, and reaeration. The closed system is more environmentally sound than the open systems.

Coastal lakes and estuaries are the most frequently used off-shore sites for rearing units, but it is becoming more common to see units located at sea. There are four basic types of cages used for off-shore fish-farming operations. They are fixed, floating, submersible, and submerged. Fixed cages are made of net or webbing material and supported by posts that are anchored in the river bottom. Floating cages, also known as net pens, are the most common type of cage used. Developed in Norway, they are made of net or rigid mesh and are supported by a buoyant collar. Submersible cages have a frame which enables them to hold their shape made of net or rigid mesh and are supported by a buoyant collar. Submerged cages are usually made of wood and anchored in place.

One major concern about off-shore nets and pens is that they tend to attract marine birds and mammals, which attempt to get at the fish with often fatal results. Fish farmers currently use wire barriers and electrical devices to discourage predators and these devices have killed **sea lions**. A typical four-acre salmon farm holds 75,000 fish, and the amount of **organic waste** produced is equal to that of a town with 20,000 people. Waste matter then settles on the ocean floor, where it disrupts the normal **ecosystem**. Accumulated wastes kill clams, oysters and other shellfish, and also causes a proliferation of algae, **fungi**, and **parasites**, as well as **plankton** bloom. Plankton bloom is dangerous to sea life and to humans. In order to control the algae and plankton farmers treat the fish and the water with numerous **chemicals** such as **copper** sulfate and formalin. These chemicals do not act exclusively on algae, killing many other beneficial forms of aquatic life and disrupting the ecological balance. According to the **Sierra Club** Legal Defense Fund, the pens qualify as point sources of **pollution** and should fall under the **Clean Water Act**. At this point in time, however, the pens do not come under the jurisdiction of the act.

Many fish on farms are raised from eggs imported from other areas. Farm-raised fish can and do escape from their pens, causing havoc with local ecosystems. The interbreeding of imported fish with indigenous species can alter the genetic traits that allow the indigenous species to survive in that particular location. Farm-raised stock that escapes and reproduces may also compete with native species, resulting in the decline of wild fish in that particular area. Off the coast of Norway for example, the offspring of escaped farm-raised salmon outnumber the indigenous species.

There are many questions about health and nutrition that may affect consumers of farm-raised fish. Fish farmers frequently use large quantities of medications to keep the fish healthy and there are concerns over the effects that these medications have on human health. Possible side effects of eating farm-raised fish on a regular basis include allergic reactions, increased incidence of infections by resistant bacterial strains, and suppressed immune system response. If eaten by pregnant women there is evidence of fetal damage, discoloration of infants teeth, and abnormal bone growth. Omega-3 fatty acids are a beneficial part of our diet and they are present in the flesh of wild salmon and in some other fish, but not in their farm-raised counterparts. Recent studies have found that farm-raised salmon and catfish contained twice the amount of fat found in wild species. Other comparative nutritional studies are currently underway.

Fish farming is a relatively new industry that shows a lot of potential, but there are many environmental and health questions that need to be addressed. Monitoring of the industry is virtually non-existent. In the United States, the Joint Subcommittee on Aquaculture (JSA) has made recommendations for additional studies of the industry including the environmental impact of fish farming. JSA has pointed out the need for extensive research into the life cycle of parasites and diseases that **plague** fish. They have recommended drug and chemical testing as well as registration procedures. In the 1983 report issued by JSA every aspect of the farming operation was cited as needing additional studies. *See also* Agricultural pollution; Algal bloom; Aquatic chemistry; Aquatic weed control; Commercial fishing; Feedlot runoff; Marine pollution; Water quality standards

Blue-baby syndrome

Blue-baby syndrome (or infant cyanosis) occurs in infants who drink water with a high concentration of nitrate or are fed formula prepared with water containing high nitrate levels. Excess nitrate can result in methemoglobinemia, a

condition in which the oxygen-carrying capacity of the blood is impaired by an **oxidizing agent** such as nitrite, which can be reduced from nitrate by bacterial **metabolism** in the human mouth and stomach. Infants in the first three to six months of life, especially those with diarrhea, are particularly susceptible to nitrite-induced methemoglobinemia.

Adults convert about 10% of ingested **nitrates** into **nitrites**, and excess nitrate is excreted by the kidneys. In infants, however, nitrate is transformed to nitrite with almost 100% efficiency. The nitrite and remaining nitrate are absorbed into the body through the intestine. Nitrite in the blood reacts with hemoglobin to form methemoglobin, which does not transport oxygen to the tissues and body organs. The skin of the infant appears blue due to the lack of oxygen in the blood supply, which may lead to asphyxia, or suffocation.

Normal methemoglobin levels in humans range from 1 to 2%; levels greater than 3% are defined as methemoglobinemia. Methemoglobinemia is rarely fatal, readily diagnosed, and rapidly reversible with clinical treatment.

In adults, the major source of nitrate is dietary, with only about 13% of daily intake from drinking water. Nitrates occur naturally in many foods, especially vegetables, and are often added to meat products as preservatives. Only a few cases of methemoglobinemia have been associated with foods high in nitrate or nitrite. Nitrate is also found in air, but the daily respiratory intake of nitrate is small compared with other sources. Nearly all cases of the disease have resulted from ingestion by infants of nitrate in private well water that has been used to prepare infant formula. Levels of nitrate of three times the Maximum Contaminant Levels (MCLs) and above have been found in drinking water **wells** in agricultural areas. Federal MCL standards apply to all public water systems, though they are unenforceable recommendations. Insufficient data are available to determine whether subtle or chronic toxic effects may occur at levels of exposure below those that produce clinically obvious toxicity. If water has or is suspected to have high nitrate concentrations, it should not be used for infant feeding, nor should pregnant women or nursing mothers be allowed to drink it.

Domestic water supply wells may become contaminated with nitrate from mineralization of **soil** organic **nitrogen**, **septic tank** systems, and some agricultural practices, including the use of fertilizers and the disposal of animal wastes. Since there are many potential sources of nitrates in **groundwater**, the prevention of nitrate contamination is complex and often difficult.

Nitrates and nitrites can be removed from drinking water using several types of technologies. The **Environmental Protection Agency** (EPA) has designated reverse osmosis, anion exchange, and electrodialysis as the **Best Available Control Technology** (BAT) for the removal of nitrate, while recommending reverse osmosis and anion exchange as the BAT for nitrite. Other technologies can be used to meet MCLs for nitrate and nitrite if they receive approval from the appropriate state regulatory agency.

Murray Bookchin (1921 –)

American social critic, environmentalist, and writer

Born in New York in 1921, Bookchin is a writer, social critic, and founder of "social ecology." He has had a long and abiding interest in the **environment**, and as early as the 1950s he was concerned with the effects of human actions on the environment. In 1951 he published an article entitled "The Problem of Chemicals," which exposed the detrimental effects of **chemicals** on **nature** and on human health. This work predates **Rachel Carson's** famous *Silent Spring* by over 10 years.

Murray Bookchin. (Photograph by Debbie Bookchin. Reproduced by permission.)

In developing his theory of **social ecology**, Bookchin makes the basic point that "you can't have sound ecological practices in nature without having sound social practices in society. Harmony in society means harmony with nature." Bookchin describes himself as an anarchist, contending that "there is a natural relationship between natural **ecology** and anarchy."

Bookchin has long been a critic of modern cities: his widely read and frequently quoted *Crisis in Our Cities* (1965) examines urban life, questioning "the lack of standards in judging the modern metropolis and the society that fosters its growth." His *The Rise of Urbanization and the Decline of Citizenship* (1987) continues the critique by advancing green ideas as a new municipal agenda for the 1990s and the next century. Though he is often mentioned as one of its founding thinkers, Bookchin is an ardent critic of **deep ecology**. He states: "Bluntly speaking, deep ecology, despite all its social rhetoric, has no real sense that our ecological problems have their roots in society and in social problems." Bookchin instead reaffirms a social ecology that is, first of all "social," incorporating people into the calculus needed to solve environmental problems, "avowedly rational," "revolutionary, not merely 'radical,'" and "radically" green.

Norman E. Borlaug (1914 –)

American environmental activist

Borlaug, known as the father of the "green revolution" or **agricultural revolution**, was born on March 25, 1914, on a small farm near Cresco, Iowa. He received a B.S. in forestry in 1937 followed by a master's degree in 1940 and a Ph.D. in 1941 in **plant pathology** all from the University of Minnesota.

Agriculture is an activity of humans with profound impact on the **environment**. Traditional cereal grain production methods in some countries have led to recurrent **famine**. Food in these countries can be increased either by expansion of land area under cultivation or by enhancement of crop yield per unit of land. In many developing countries, little if any space for agricultural expansion remains, hence interest is focused on increasing cereal grain yield. This is especially true with regard to wheat, rice, and maize.

Borlaug is associated with the green revolution which was responsible for spectacular increases in grain production. He began working in Mexico in 1943 with the Rockefeller Foundation and the International Maize and Wheat Improvement Center in an effort to increase food crop production. As a result of these efforts, wheat production doubled in the decade after World War II, and nations such as Mexico, India, and Pakistan became exporters of grain rather than importers. Increased yields of wheat came as the result of high genetic yield potential, enhanced disease **resistance** (Mexican wheat was vulnerable to stem rust fungus), responsiveness to fertilizers, the use of pesticides, and the development of dwarf varieties with stiff straw and short blades that resist lodging, i.e., do not grow tall and topple over with the use of **fertilizer**. Further, the new varieties could be used in different parts of the world because they were unaffected

Norman Borlaug. (Corbis-Bettmann. Reproduced by permission.)

by different daylight periods. Mechanized threshing is now replacing the traditional treading out of grain with large animals followed by winnowing because these procedures are slow and leave the grain harvest vulnerable to rain damage. Thus, modern threshers are an essential part of the green revolution.

Borlaug demonstrated that the famine so characteristic of many developing countries could be controlled or eliminated at least with respect to the population of the world at that time. However, respite from famine and poverty is only temporary as the world population relentlessly continues to increase. The sociological and economic conditions which have historically precipitated famine have not been abrogated. Thus, famine will appear again if human population expansion continues unabated despite efforts of the green revolution. Further, critics of Borlaug's agricultural revolution cite the possibility of crop vulnerability because of genetic uniformity—development of crops with high-yield potential have eliminated other varieties, thus limiting **biodiversity**. High-yield crops have not proven themselves hardier in several cases; some varieties are more vulnerable to molds and storage problems. In the meantime, other, hardier varieties are now nonexistent. The environmental effects of fertilizers, pesticides, and energy-dependent mechanized modes of cultivation to sustain the newly developed crops have also provoked controversy. Such methods are expensive for poorer countries and sometimes create more problems than they solve. For now, however, food from the green revolution saves lives and the benefits currently outweigh liabilities.

At the presentation of the Nobel Peace Prize to Borlaug in 1970, the president of Norway's Lating honored him, saying "more than any other single person of this age, he has helped to provide bread for a hungry world." His alma mater, the University of Minnesota, celebrated his career accomplishments with the award of a Doctor of Science (*honoris causa*) degree in 1984, as have many other academic institutions throughout a grateful world.

In 1992, the Agricultural Council of Experts (ACE) was formed to advise Borlaug and former President Jimmy Carter on information concerning Africa's agricultural and economic issues. They created a model that has since been incorporated into the Global 2000 program, which addresses the African food crisis by experimenting with production test plots (PTPs) in an attempt to extract greater crop yields.

Boston Harbor clean up

Like many harbors near cities along the eastern seaboard, the Boston Harbor in Massachusetts has been used for centuries as a receptacle for raw and partially treated sewage from the city of Boston and surrounding towns. In the late 1800s, Boston designed a sewage and stormwater collection system. This sewage system combined millions of gallons of untreated sewage from homes, schools, hospitals, factories, and other buildings with stormwater collected from streets during periods of moderate to heavy rainfall. The combined sewage and stormwater collected in the sewage system was discharged untreated to Boston Harbor on outgoing tides. Sewage from communities surrounding Boston was also piped to Boston's collection system and discharged to Boston Harbor and the major rivers leading to it: the Charles, Mystic, and Neponset Rivers. Many of the sewage pipes, tunnels,

and other infrastructure built in the late 1800s and early 1900s are still in use today.

In the 1950s, the City of Boston was concerned with growing health risks of swimming in and eating shellfish harvested from Boston Harbor as well as odors and aesthetic concerns that resulted from discharging raw sewage into Harbor waters. The city built two advanced primary **sewage treatment** plants during the 1950s and 1960s on two islands located in Boston Harbor. The first sewage treatment plant was built on Nut Island; it treated approximately 110 million gal/per day (416 million l/per day). The second sewage treatment plant was built on Deer Island; it treated approximately 280 million gal/per day (1060 million l/per day). The two sewage treatment plants removed approximately half the total suspended solids and 25% of the biological oxygen demand found in raw sewage. The outgoing tide in Boston Harbor was still used to flush the treated **wastewater** and approximately 50 tons (46 metric tons) per day of sewage **sludge** (also called biosolids), which was produced as a byproduct of the advanced primary treatment process. The sewage sludge forms from solids in the sewage settling in the bottom of tanks.

During the 1960s, the resources devoted to maintaining the City's aging sewage system decreased. As a result, the sewage treatment plants, pipes, pump stations, tunnels, interceptors, and other key components of Boston's sewage infrastructure began to fall into disrepair. Equipment breakdowns, sewer line breaks, and other problems resulted in the **discharge** of raw and partially treated sewage to Boston Harbor and the rivers leading to it. During this time, the Metropolitan District Commission (MDC) was the agency responsible for sewage collection, treatment, and disposal.

In 1972, the United States Congress enacted the **Clean Water Act**. This was landmark legislation to improve the quality of our nation's waters. The Clean Water Act required that sewage discharged to United States waters must meet secondary treatment levels by 1977. Secondary treatment of sewage means that at least 85% of total suspended solids and 85% of biological oxygen demand is removed from sewage. Instead of working towards meeting this federal requirement, the MDC requested a waiver from this new obligation from the United States **Environmental Protection Agency** (EPA). In 1983, the EPA denied the waiver request. The MDC responded by modifying its waiver request to promise that the city would construct a 9.2 mi (14.8 km) outfall to achieve increased dilution of the sewage by discharging to deeper, more flushed waters. As part of its waiver, MDC also promised an end to discharging sewage sludge in the harbor and initiation of a combined sewer overflow abatement project to cease flow into Boston Harbor from 88 overflow pipes. In 1985, EPA denied the second waiver request.

During EPA's consideration of Boston's waiver request, in 1982, the City of Quincy filed a lawsuit against the MDC for violating the Clean Water Act. In 1983, the Conservation Law Foundation filed two lawsuits; one was against MDC for violating the Clean Water Act and the other was against EPA for not fully implementing the Clean Water Act by failing to get Boston to comply with the law. The Massachusetts legislature responded to these pressures by replacing the MDC with the Massachusetts **Water Resources** Authority (MWRA) in 1984. The MWRA was created as an independent agency with the authority to raise water and sewer rates to pay for upgrading and maintaining the collection and treatment of the region's sewage. The following year, the federal court ruled that the MWRA must come into compliance with the Clean Water Act. As a result of this ruling, the MWRA developed a list of sewage improvement projects that were necessary to upgrade the existing sewage treatment system and clean up Boston Harbor.

The Boston Harbor clean up consists of $3.4 billion worth of sewage treatment improvements that include the construction of a 1,270 million-gal/per day (4,800 million-l/per day) primary sewage treatment plant, a 1,080 million-gal/per day (4,080 million-l/per day) secondary sewage treatment plant, a dozen sewage sludge digesters, disinfection basins, a sewage screening facility, an underwater tunnel, a 9.5 mi-long (15.3 km) outfall pipe, 10 pumping stations, a sludge-to-fertilizer facility, and combined sewer overflow treatment facilities.

Today, approximately 370 million gallons/per day (1,400 million l/per day) of sewage **effluent** from over 2.5 million residents and businesses is discharged to Boston Harbor. Almost half the total flow is stormwater **runoff** from streets and **groundwater** infiltrating into cracked sewer pipes. The combined sewage and stormwater is moved through 5,400 mi (8,700 km) of pipes by gravity and with the help of pumps. Five of the 10 pumps have already been replaced. At least two of the pumping stations that were replaced as part of the clean up effort dated back to 1895. The sewage is pumped to Nut Island where more than 10,000 gal/per day (37,800 l/per day) of floatable **pollution** such as grease, oil, and plastic debris are now removed by its new sewage screening facility. The facility also removes any grit, sand, gravel, or large objects. A 4.8-mi (7.7-km) long deep-rock tunnel will be used to transport screened wastewater to Deer Island for further treatment.

One of the most significant changes that has occurred as part of the Boston Harbor clean up project is the reconstruction of Deer Island. Prior to 1989, Deer Island had prison buildings, World War II army bunkers, and an aging sewage treatment plant. All the old buildings and structures have been removed and the island has been reshaped to

accommodate 12 massive sewage sludge digesters, 60 acres (24.2 ha) of a new primary sewage treatment plant, and a new secondary treatment facility. The primary sewage treatment plant has reduced the amount of suspended solids discharged to Boston Harbor from 138–57 tons per day (126–52 metric tons).

The secondary sewage treatment plant on Deer Island is still under construction. It will use settling tanks, as are found in primary sewage treatment plants, as well as **microorganisms**, which will consume organic matter in the sewage thereby increasing treatment levels. Secondary treatment of Boston's sewage will result in an increase in removal of total suspended solids from 50–90% and biological oxygen demand from 25–90%. The first phase of the secondary treatment plant construction was completed by the end of 1997.

After the sewage is treated and disinfected to remove any remaining pathogens (disease-causing organisms), the effluent is discharged through a 9.5 mi (15.3 km) long outfall tunnel into the waters of Massachusetts Bay. Massive tunnel boring machines were used to drill the tunnel below the ocean floor. The outfall has 55 diffuser pipes connected at right angles to it along the last 1.25 mi (2.01 km) of the outfall. The diffuser pipes will increase dispersion of the treated sewage in the receiving waters. The tunnel was opened in September of 2000.

The outfall has been a source of controversy for many residents of Cape Cod and for the users of Massachusetts Bay and the Gulf of Maine. There is concern about the long-term impact of contaminants from the treated sewage on the area, which is used for **transportation**, **recreation**, fishing, and tourism. Some alternatives to the sewage treatment plant and the 9.5-mi (15.3-km) long outfall pipe were developed by civil engineers at the Massachusetts Institute of Technology. The alternatives included modifications to the advanced primary treatment facility and a smaller secondary treatment facility with the effluent discharged to Boston Harbor. Because there was not enough evidence to convince EPA that **water quality standards** would always be met in the harbor, EPA rejected the alternatives.

As part of the Boston Harbor clean up, sewage sludge is no longer discharged to the harbor. Twelve sewage sludge digesters in Deer Island were constructed in 1991. The digesters break down the sewage sludge by using microorganisms such as bacteria. Different types of microorganisms are used in the sewage sludge digestion process than in the secondary treatment process. As the microorganisms consume the sewage sludge, **methane** gas is produced which is used for heat and power. Prior to 1991, all the sewage sludge was discharged to Boston Harbor. Since 1991, the sewage sludge has been shipped to a facility that converts the digested sewage sludge into **fertilizer**.

The sludge-to-fertilizer facility dewaters the sludge and uses rotating, high temperature dryers that produce fertilizer pellets with 60% organic matter, and important nutrients such as **nitrogen**, **phosphorus**, calcium, sulfur, and iron. The fertilizer is marketed in bulk and also sold as *Bay State Organic*, which is sold locally for use on **golf courses** and landscape.

This massive undertaking to clean up the harbor by upgrading its sewage treatment facilities is one of the world's largest public works projects. Over 80% of the Boston Harbor clean up is completed. These changes have resulted in measurable improvements to Boston Harbor. The harbor sustains a $10 million lobster fishery annually as well as flounder, striped bass, cod, bluefish, and smelt recreational fisheries.

Botanical garden

A botanical garden is a place where collections of plants are grown, managed, and maintained. Plants are normally labeled and available for scientific study by students and observation by the public. An arboretum is a garden composed primarily of trees, vines and shrubs. Gardens often preserve collections of stored seeds in special facilities referred to as seed banks. Many gardens maintain special collections of preserved plants, known as herbaria, used to identify and classify unknown plants. Laboratories for the scientific study of plants and classrooms are also common.

Although landscape gardens have been known for as long as 4,000 years, gardens intended for scientific study have a more recent origin. Kindled by the need for herbal medicines in the sixteenth century, gardens affiliated with Italian medical schools were founded in Pisa about 1543, and Padua in 1545. The usefulness of these medicinal gardens was soon evident, and similar gardens were established in Copenhagen, Denmark (1600), London, England (1606), Paris, France (1635), Berlin, Germany (1679), and elsewhere. The early European gardens concentrated mainly on **species** with known medical significance. The plant

collections were put to use to make and test medicines and to train students in their application.

In the eighteenth and nineteenth centuries, gardens evolved from traditional herbal collections to facilities with broader interests. Some gardens, notably the Royal Botanic Gardens at Kew, near London, played a major role in spreading the cultivation of commercially important plants such as coffee (*Coffea arabica*), **rubber** (*Hevea* spp.), banana (*Musa paradisiaca*), and tea (*Thea sinensis*) from their places of origin to other areas with an appropriate **climate**. Other gardens focused on new varieties of horticultural plants. The Leiden garden in Holland, for instance, was instrumental in stimulating the development of the extensive worldwide Dutch bulb commerce. Many other gardens have had an important place in the scientific study of plant diversity as well as the introduction and assessment of plants for agriculture, horticulture, forestry, and medicine.

The total number of botanical gardens in the world can only be estimated, but not all plant collections qualify for the designation because they are deemed to lack serious scientific purpose. A recent estimate places the number of botanical gardens and arboreta at 1,400. About 300 of those are in the United States. Most existing gardens are located in the North Temperate Zone, but there are important gardens on all continents except **Antarctica**. Although the tropics are home to the vast majority of all plant species, until recently, relatively few gardens were located there. A recognition of the need for further study of the diverse tropical **flora** has led to the establishment of many new gardens. An estimated 230 gardens are now established in the tropics.

In recent years botanical gardens throughout the world have united to address increasing threats to the planet's flora. The problem is particularly acute in the tropics, where as many as 60,000 species, nearly one-fourth of the world's total, risk **extinction** by the year 2050. Botanical gardens have organized to produce, adopt and implement a Botanic Gardens Conservation Strategy to help deal with the dilemma. *See also* Conservation; Critical habitat; Ecosystem; Endangered species; Forest decline; Organic gardening and farming

Kenneth Ewart Boulding (1910 – 1993)

English economist, social scientist, writer, and peace activist

Kenneth Boulding is a highly respected economist, educator, author, and pacifist. In an essay in *Frontiers in Social Thought: Essays in Honor of Kenneth E. Boulding* (1976), Cynthia Earl Kerman described Boulding as "a person who grew up in the poverty-stricken 'inner city' of Liverpool, broke through the class system to achieve an excellent education, had both scientific and literary leanings, became a well-known American economist, then snapped the bonds of economics to extend his thinking into wide-ranging fields—a person who is a religious mystic and a poet as well as a social scientist."

A major recurring theme in Boulding's work is the need—and the quest—for an integrated social science, even a unified science. He does not see the disciplines of human knowledge as distinct entities, but rather a unified whole characterized by "a diversity of methodologies of learning and testing." For example, Boulding is a firm advocate of adopting an ecological approach to economics, asserting that **ecology** and economics are not independent fields of study. He has identified five basic similarities between the two disciplines: 1) both are concerned not only with individuals, but individuals as members of **species**; 2) both have an important concept of dynamic equilibrium; 3) a system of exchange among various individuals and species is essential in both ecological and economic systems; 4) both involve some sort of development—succession in ecology and **population growth** and capital accumulation in economics; 5) both involve distortion of the equilibrium of systems by humans in their own favor.

"If my life philosophy can be summed up in a sentence," Boulding stated, "it is that I believe that there is such a thing as human betterment—a magnificent, multidimensional, complex structure—a cathedral of the mind—and I think human decisions should be judged by the extent to which they promote it. This involves seeing the world as a total system." Boulding's views have been influential in many fields, and he has helped environmentalists reassess and redefine their role in the larger context of science and economics.

Boundary Waters Canoe Area

The Boundary Waters Canoe Area (BWCA), a federally designated **wilderness** area in northern Minnesota, includes approximately one million acres (410,000 ha) stretching some 200 mi (322 km) along the United States-Canadian border. The BWCA contains more than 1,200 mi (1,932 km) of canoe routes and portages. The second largest expanse in the National Wilderness Preservation system, the BWCA is administered by the United States **Forest Service**. Constituting about one-third of the Superior **National Forest** (established in 1909), the BWCA was set apart as wilderness by an act of Congress in 1958. The 1964 **Wilderness Act** allowed limited **logging** in some parts of the BWCA and the use of motorboats on 60% of the water area. Under pressure from environmental groups—and over objections by developers, logging interests, and many local residents—the Congress finally passed the BWCA Wilderness Act of 1978, which outlawed all logging and limited motorboats to 33% of the water surface area (due to drop to 24% by 1999), and added 45,000 acres (18,450 ha), bringing the total area to 1,075,000 acres (440,750 ha).

Many area residents and resort owners continue to resent and resist efforts to reduce the areas open to motorized watercraft and snowmobile traffic. They have pressed unsuccessfully for federal legislation to that effect. At the urging of Senator Paul Wellstone (D-MN), a mediation panel was convened in 1996 to consider the future of the BWCA. Environmentalists, resort owners, local residents, and representatives of other groups met for several months to try to reconcile competing interests in the area. Unable to reach agreement and arrive at a compromise, the panel disbanded in 1997. The fierce and continuing political quarrels over the future of the BWCA contrast markedly with the silence and serenity of this land of sky-blue waters and green forests.

Brackish

The **salinity** of brackish water is intermediate between seawater and fresh waters. Brackish water contains too much salt to be drinkable, but not enough salt to be considered seawater. The ocean has an average salinity of 35 parts per thousand (ppt), whereas freshwater contains 0.065–0.30 ppt of salts, primarily chloride, sodium, sulfate, magnesium, calcium, and potassium ions. The salt content of brackish water ranges between approximately 0.50 and 17 ppt. Brackish water occurs where freshwater flows into the ocean, or where salts are dissolved from subsoils and percolate into freshwater basins. The gradient between salt and fresh water in estuaries and deltas varies from sharp distinction to gradual mixing, and different levels of vertical and horizontal mixing depend on the influence of tide, current, and rate of freshwater inflow.

BRDs

see **Bycatch Reduction Devices**

Broad spectrum pesticide

see **Pesticide**

Bromine

Bromine is an element that belongs to Group 17 on the periodic table of elements, the group that contains substances called halogens. Other halogens include fluorine, **chlorine**, and iodine. Halogens are important elements that are used in heavily in industry. Bromine is used in the manufacture of dyes, fumigants, fire-retardant materials, medicines, pesticides, and photographic emulsions. Bromine is also used for water purification. While bromine and bromine-containing products are very useful, some concern surrounds the use of some bromine compounds because of their impact on the **environment**, particularly the **ozone** layer.

The many uses of bromine are due to its chemical properties. The halogens are the most reactive non-metal elements in the periodic table. Halogens characteristically react very rapidly and readily with almost all metals to form salts. The high reactivity of the halogens is due to the presence of seven (rather than the stable noble-gas configuration of eight) electrons in their outer shell. Thus, they have an unpaired electron that is readily available for chemical bonding and reactions with other elements. Unlike chlorine and iodine, bromine is a liquid at room temperature. It is the only liquid nonmetallic element.

Bromine is a fairly heavy inorganic element. First isolated in 1826, the atomic number of bromine is 35, which means it has 35 electrons and 35 protons. Bromine also contains 45 neutrons in its nucleus, making its average atomic mass 79.9 atomic mass units. At room temperature, it is a reddish-brown liquid that emits pungent, noxious fumes that irritate the eyes. Appropriately, the word *bromine* is derived from the Greek word *bromos*, which means "stench." Bromine readily dissolves in water and **carbon** disulfide. It has a boiling point of 138.6°F(59.2°C) and is more reactive than iodine, but less reactive than chlorine. When bromine chemically reacts with other elements or compounds, it has a bleaching effect. It is a fairly strong **oxidizing agent**. Relative to the other halogens, bromine is a stronger oxidizing agent than iodine, but a weaker oxidizer than both chlorine and fluorine. Even so, liquid bromine is very caustic and can seriously damage skin on contact. Bromine, like the other halogens, has a very high affinity for itself, and therefore forms diatomic molecules, which are molecules that contain only two atoms. Molecular bromine exists as two bromine atoms bonded together.

Bromine is obtained from natural salt deposits. Two areas within the United States that have historically been associated with bromine extraction are Arkansas and Michigan. Bromine may also be extracted from seawater. Aqueous bromine may also be produced from the oxidation of bromides during **chlorination** of water, especially when seawater is used as a coolant. Since it contains a very slight concentration of bromine salts (about 85 **parts per million**), seawater is not a major source of industrial bromine. The most common form of mineralized bromine is silver bromide (bromargyrite), found chiefly in Mexico and Chile. Most of the supply of bromine used for industrial purposes, however, comes from the United States and Israel, with smaller amounts produced in France, Japan, and Russia.

Bromine-containing substances have been used for centuries. The first use of a material containing bromine was in ancient Rome. During the Roman Empire, a highly prized purple dye was painstakingly extracted from marine mussels. The dye, a bromine compound, was very expensive because it was so difficult to obtain and only the very wealthy could afford clothing dyed with the hue of this dye, which resulted in the term "royal purple." Nowadays, bromine is used not only the production of dyes, but also in the production of **chemicals** that improve safety, agriculture, and **sanitation**.

Bromine is a very effective agent in controlling the growth of aquatic **microorganisms**. As such, and like chlorine, it is used for **water treatment** because it can kill microorganisms and keep water clear and free from foul odors. For example, bromine salts, like sodium bromide, are used to control the growth of algae and bacteria in recreational spaces like hot tubs and swimming pools. Another common bromine aquatic biocide is bromochlorodimethylhydantoin. Occasionally, bromine is used by municipalities to control disease-causing **microbes** in drinking water because some of these microorganisms are more susceptible to bromine than chlorine.

Bromine compounds are also used as pesticides. Like other halogenated **hydrocarbons** such as DDT, some brominated hydrocarbons are powerful insecticides. A very effective and important bromine-containing hydrocarbon **pesticide** is methyl bromide. This agent, also known as bromomethane, is used to fumigate stored grain and produce to free them from **pest** infestations. Methyl bromide is also used to fumigate **soil** for valuable crops like strawberries, peppers, eggplants, tomatoes, and **tobacco**. Since the 1940s, methyl bromide has been used as a soil pretreatment to

kill insect, roundworm, and weed **species** that decrease the productivity of economically important crops. In 1992, approximately 73,000 tons of methyl bromide were used. However it was discovered that methyl bromide, like **chlorofluorocarbons**, also contributes to the depletion of the ozone layer. As a result, the **Environmental Protection Agency** (EPA) made recommendations that its use be phased-out based upon the expert assessments of atmospheric scientists from the World Meteorological Organization and the **National Oceanic and Atmospheric Administration**. Under the **Clean Air Act**, the EPA is enforcing reductions in the use of methyl bromide. A mandatory reduction of 25% was achieved in 1999. By 2001, 50% reduction had been enforced. By the year 2003, a 70% reduction in the use of methyl bromide must be attained with a goal for a complete ban of the compound scheduled for the year 2005.

Despite the ban on methyl bromide, bromine will continue to be a valued chemical. The pharmaceutical industry relies heavily on bromine both in the manufacturing process and as constituent substance in pharmaceutical agents. The general anesthetic, halothane, contains bromine. The production of naproxen sodium, an over-the-counter non-steroidal analgesic, uses bromine in intermediate reactions. Brompheniramine, the widely available antihistamine cold and allergy medication, contains bromine. The synthetic addition of bromine, or other halogens, to medications such as these facilitates their uptake into tissues. Other drugs use bromine to create easily absorbed dosage forms. For example, dextromethorphan hydrobromide, a cough medication, is a soluble bromine salt form of the poorly soluble active drug dextromethorphan, and dissolves easily as a clear solution.

Bromine is also used to create fire-resistant **plastics**. Plastic is made of very flammable hydrocarbon polymers. The addition of bromine compounds creates fire-retardant plastic products. Brominated flame-retardants are used in televisions, stereos, computers, and electrical wiring to reduce fire hazard when these common electronic appliances generate excessive heat. Brommine-containing fire-retardant chemicals are also used in carpeting, draperies, and furniture foam padding. While bromine compounds make products more fire-resistant, they do not make them fire-proof. Rather, they reduce the likelihood that a plastic item will ignite and delay the spread of fire. As bromine-treated plastic products burn, they release brominated hydrocarbons that threaten the ozone layer not unlike chorofluorocarbons (CFCs). For this reason, research is now directed at finding alternatives to bromine flame-retardant chemicals. For example, promising new fire-resistant compounds use silicon.

Aside from its use in dyes, pesticides, water treatment, pharmaceuticals, and fire retardants, bromine compounds are also used in photographic film and print paper emulsions, hydraulic fluids, refrigeration fluids, inks, and hair products. As useful as bromine is, however, concern for the ozone layer has resulted in heightened vigilance concerning the overuse of bromine-containing chemicals.

Bronchial constriction

see **Asthma**

Bronchitis

Chronic bronchitis is a persistent inflammation of the bronchial tubes, airways leading to the lungs. The disease is characterized by a daily cough that produces sputum for at least three months each year for two consecutive years, when no other disease can account for these symptoms. The diagnosis of chronic bronchitis is made by this history, rather than by any abnormalities found on a chest x-ray or through a pulmonary function test.

When a person breathes in, air, **smoke**, germs, allergens, and pollutants pass from the nose and mouth into a large central duct called the trachea. The trachea branches into smaller ducts, the bronchi and bronchioles, which lead to the alveoli. These are the tiny, balloonlike, air sacs, composed of capillaries, supported by connecting tissue, and enclosed in a thin membrane. Bronchitis can permanently damage the alveoli.

Bronchitis is usually caused by **cigarette smoke** or exposure to other irritants or air pollutants. The lungs respond to the irritation in one of two ways. They may become permanently inflamed with fluid, which swells the tissue that lines the airways, narrowing them and making them

resist airflow. Or, the mucus cells of the bronchial tree may produce excessive mucus.

The first sign of excessive mucus production is usually a morning cough. As smoking or exposure to air pollutants continues, the irritation increases and is complicated by infection, as excess mucus provides food for bacteria growth. The mucus changes from clear to yellow, and the infection becomes deep enough to cause actual destruction of the bronchial wall. Scar tissue replaces the fine cells, or cilia, lining the bronchial tree, and some bronchioles are completely destroyed. Paralysis of the cilia permits mucus to accumulate in smaller airways, and air can no longer rush out of these airways fast enough to create a powerful cough.

With each pulmonary infection, excess mucus creeps into the alveoli, and on its way, totally blocking portions of the bronchial tree. Little or no gas exchange occurs in the alveoli, and the ventilation-blood flow imbalance significantly reduces oxygen levels in the blood and raises **carbon dioxide** levels. Chronic bronchitis eventually results in airway or air sac damage; the air sacs become permanently hyperinflated because mucus obstructing the bronchioles prevents the air sacs from fully emptying.

Chronic bronchitis usually goes hand-in-hand with the development of **emphysema**, another chronic lung disease. These progressive diseases cannot be cured, but can be treated. Treatment includes avoiding the inhalation of harmful substances such as polluted air or cigarette smoke.

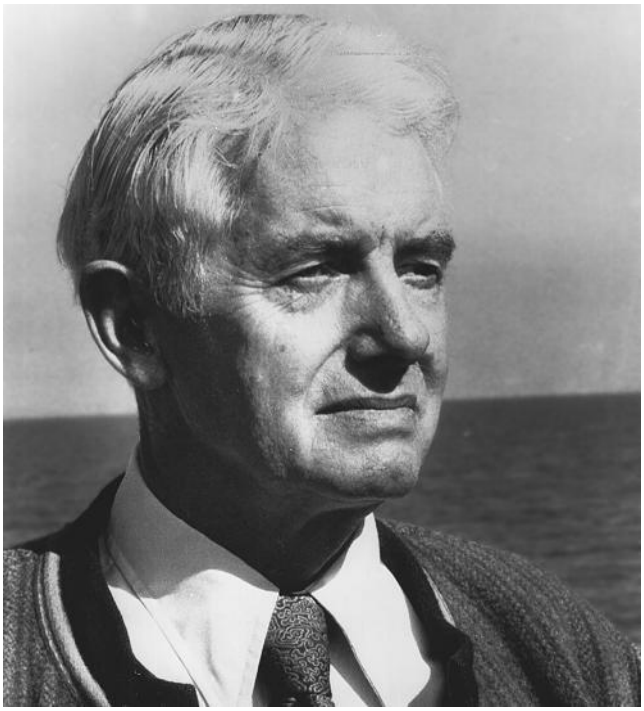
David Ross Brower (1912 – 2000)

American environmentalist and conservationist



David R. Brower, the founder of both **Friends of the Earth** and the **Earth Island Institute**, has long been widely considered to be one of the most radical and effective environmentalists in the United States.

Joining the **Sierra Club** in 1933, Brower became a member of its Board of Directors in 1941 and then its first executive director, serving from 1952 to 1969. In this position, Brower helped transform the group from a regional to a national force, seeing the club's membership expand from 2,000 to 77,000 and playing a key role in the formation of the Sierra Club Foundation. Under Brower's leadership the Sierra Club, among other achievements, successfully opposed the Bureau of Reclamation's plans to build **dams** in Dinosaur National Monument in Utah and Colorado as well as in Arizona's Grand Canyon, but lost the fight to preserve Utah's Glen Canyon. The loss of Glen Canyon became a kind of turning point for Brower, indicating to him the need to take uncompromising and sometimes militant stands in defense of the natural **environment**. This militancy occasionally caused friction both between the groups he has led and the private corporations and governmental agencies with which they interact and also within the increasingly broad-based groups themselves. In 1969 Brower was asked to resign as executive director of the Sierra Club's Board of Directors, which disagreed with Brower's opposition to a nuclear reactor in California's Diablo Canyon, among other differences. Eventually reelected to the Sierra Club's Board in 1983 and 1986, Brower is now an honorary vice-president of the club and was the recipient, in 1977, of the **John Muir** Award, the organization's highest honor.

After leaving the Sierra Club in 1969, Brower founded Friends of the Earth with the intention of creating an environmental organization that would be more international in scope and concern and more political in its orientation than the Sierra Club. Friends of the Earth, which now is operating in some 50 countries, was intended to pursue a more global vision of **environmentalism** and to take more controversial stands on issues—including opposition to nuclear weapons—than could the larger, generally more conservative organization. But in the early 1980s, Brower again had a falling out with his associates over policy, eventually resigning from Friends of the Earth in 1986 to devote more of his time and energy to the Earth Island Institute, a San Francisco-based organization he founded in 1982 and of which he is presently chairman.

Over the years, Brower played a key role in preserving **wilderness** in the United States, helping to create national park's and national seashores in Kings Canyon, the North Cascades, the **Redwoods**, Cape Cod, Fire Island, and Point Reyes. He also was instrumental in protecting primeval forests in the Olympic **National Park** and wilderness on San Gorgonio Mountain in California and in establishing the National Wilderness Preservation System and the Outdoor **Recreation** Resources Review, which resulted in the Land and **Water Conservation** Fund.

In his youth, Brower was one of this country's foremost rock climbers, leading the historic first ascent of New Mexico's Shiprock in 1939 and making 70 other first ascents in **Yosemite National Park** and the High Sierra as well as joining expeditions to the Himalayas and the Canadian Rockies. A proficient skier and guide as well as a mountaineer, Brower served with the United States Mountain Troops from 1942–45, training soldiers to scale cliffs and navigate in Alpine areas and serving as a combat-intelligence officer in Italy. For his service, Brower was awarded both the Combat

David Ross Brower. (Corbis-Bettmann. Reproduced by permission.)

Infantryman's Badge and the Bronze Star, and rose in rank from private to captain before he left active duty. As a civilian, Brower employed many of the same talents and abilities to show people what he has fought so long and so hard to preserve: he initiated the knapsack, river, and wilderness threshold trips for the Sierra Club's Wilderness Outings Program, and between 1939 and 1956 led some 4,000 people into remote wilderness.

Excluding his military service, Brower was an editor at the University of California Press from 1941 to 1952. Appointed to the *Sierra Club Bulletin*'s Editorial Board in 1935, Brower eventually became the *Bulletin*'s editor, serving in this capacity for eight years. He had been involved with the publication of more than 50 environmentally oriented books each for the Sierra Club and Friends of the Earth, several of which earned him prestigious publishing industry awards. He wrote a two-volume autobiography, *For Earth's Sake* and *Work in Progress*. Brower also made several Sierra Club films, including a documentary of raft trips on the Yampa and Green Rivers designed to show people the stark beauty of Dinosaur National Monument, which at the time was threatened with **flooding** by a proposed dam.

Brower was the recipient of numerous awards and honorary degrees and serves on several boards and councils, including the Foundation on Economic Trends, the Council on National Strategy, the Council on Economic Priorities, the North Cascades **Conservation** Council, the Fate and Hope of the Earth Conferences, **Zero Population Growth**, the Committee on National Security, and **Earth Day**. He had twice been nominated for the Nobel Peace Prize. Brower has promoted environmental causes around the globe, giving dozens of lectures in 17 different countries and organizing several international conferences. In 1990, Brower's life was the subject of a PBS Video Documentary entitled *For Earth's Sake*. He also was featured in the TV documentary *Green for Life*, which focused on the 1992 Earth Summit in Rio de Janeiro.

Before his death on November 5, 2000, after battling bladder **cancer**, Brower was still actively promoting environmental causes. He devoted much of his time to his duties at the Earth Island Institute, and in promoting the activities of the International Green Circle. In 1990 and 1991, he led Green Circle delegations to Siberia's **Lake Baikal** to aid in its protection and restoration. Brower also lectured to companies and schools throughout the U.S. on Planetary Conservation Preservation and Restoration (CPR). His topics included land conservation, the economics of sustainability and the meaning of wilderness to science. Brower's book, *Let the Mountains Talk, Let the Rivers Run*, includes a credo for the earth, which reflects what Brower had hoped to accomplish with his lectures and publications: "We urge that all people now determine that an untrammeled wilderness shall remain here to testify that this generation had love for the next."

Lester R. Brown (1934 –)

American founder, president and senior researcher, Earth Policy Institute

Lester Brown is a highly respected and influential authority on global environmental issues. He founded the **Worldwatch Institute** in 1974 and served as its president until 2000. In 2001 he launched a new initiative, the Earth

Lester R. Brown. (Corbis-Bettmann. Reproduced by permission.)

Policy Institute Brown is an award-winning author of many books and articles on environmentally sustainable economic development and on environmental, agricultural, and economic problems and trends.

Brown was born in Bridgeton, New Jersey, and during high school and college, he grew tomatoes with his younger brother. At this time he developed his appreciation for nature's ability, if properly treated, to supply us with food on a regular and sustainable basis. After earning a degree in agricultural science from Rutgers University in 1955, he spent six months in rural India studying and working on agricultural projects. In 1959, he joined the U.S. Department of Agriculture's Foreign Agricultural Service as an international agricultural analyst. After receiving an M.S. in agricultural economics from the University of Maryland and a master's degree in public administration from Harvard, he went to work for Orville Freeman, the Secretary of Agriculture, as an advisor on foreign agricultural policy in 1964. In 1969, Brown helped establish the Overseas Development Council and in 1974, with the support of the Rockefeller Fund, he founded the Worldwatch Institute to analyze world conditions and problems such as **famine**, overpopulation, and **scarcity** of **natural resources**.

In 1984, Brown launched Worldwatch's annual *State of the World* report, a comprehensive and authoritative account of worldwide environmental and agricultural trends and problems. Eventually published in over 30 languages, *State of the World* is considered one of the most influential and widely read reports on public policy issues. Other Worldwatch publications initiated and overseen by Brown included *Worldwatch*, a bimonthly magazine, the *Environmental Alert* book series, and the annual *Vital Signs: The Trends That Are Shaping Our Future*. Brown has written or co-authored over a dozen books and some two dozen Worldwatch papers on various economic, agricultural, and environmental topics. Among his many awards, Brown has received a $250,000 "genius award" from the MacArthur Foundation, as well as the United Nation's 1987 environmental prize. *The Washington Post* has described him as "one of the world's most influential thinkers."

Brown has long warned that unless the United States and other nations adopt policies that are ecologically and agriculturally sustainable, the world faces a disaster of unprecedented proportions. In Worldwatch's yearly *State of the World* report, Brown tracked the impact of human activity on the **environment**, listing things like the percentage of bird **species** that were endangered, the number of days China's Yellow River was too depleted to irrigate fields in its lower reaches, the number of females being educated worldwide, and the number of cigarettes smoked per person. His reports made the ecological dimension of global economics clear and concrete. Often these reports were dire. The 1998 report, for example, discussed so-called demographic fatigue. This referred to places where population was falling, not because of a birthrate held in check by **family planning** but because many people were dying through famine, **drought**, and infectious disease. Conventional economics paid little heed to the environmental cost of development, leading to what a reviewer for the *Financial Times* called "a kind of cosy belief that the Earth's resources are unlimited...." Brown struggled to unseat that belief. He also wrote about a way out of the doom his work often foresaw. His 2001 *Eco-Economy: Building an Economy for the Earth* argued that creation of a new, ecologically aware economy, with emphasis on **renewable energy**, tax reform, redesign of cities and **transportation**, better agricultural methods and global cooperation, could alleviate much of the world's ills. Through the Earth Policy Institute's *Earth Policy Alerts*, Brown continued to add to the themes of his book. The mission of Brown's new organization was to reach policy makers and the public with information about building an environmentally sustainable economy.

Brown pelican

The brown pelican (*Pelecanus occidentalis*) is a large water bird of the family Pelicanidae that is found along both coasts of the United States, chiefly in saltwater habitats. It weighs up to 8 lb (3.5 kg) and has a wingspan of up to 7 ft (2 m). This pelican has a light brown body and a white head and neck often tinged with yellow. Its distinctive, long, flat bill and large throat pouch are adaptations for catching its primary food, schools of mid-water fishes. The brown pelican hunts while flying a dozen or more feet above the surface of the water, dropping or diving straight down into the water, and using its expandable pouch as a scoop or net to engulf its catch.

Both east and west coast populations, which are considered to be different subspecies, have shown various levels of decline over the later part of the twentieth century. It is estimated that there were 50,000 pairs of nesting brown pelicans along the Gulf coast of Texas and Louisiana in the early part of the twentieth century, but by the early 1960s, most of the Texas and all of the Louisiana populations were depleted. The main reason for the drastic decline was the use of organic pesticides, including DDT and endrin. These pesticides poisoned pelicans directly and also caused thinning of their eggshells. This eggshell thinning led to reproductive failure, because the egg were crushed during incubation. Louisiana has the distinction of being the only state to have its state bird become extinct within its borders. In 1970 the brown pelican was listed as endangered throughout its U.S. range.

During the late 1960s and early 1970s, brown pelicans from Florida were reintroduced to Louisiana, but many of these birds were doomed. Throughout the 1970s these transplanted birds were poisoned at their nesting sites at the outflow of the Mississippi River by endrin, which was used extensively upriver. In 1972 the use of DDT was banned in the U.S., and the use of endrin was sharply curtailed. Continued reintroduction of the brown pelican from Florida to Louisiana subsequently met with greater success, and the Louisiana population had grown to more than 1,000 pairs by 1989. Although the Texas, Louisiana, and California populations are still listed as endangered, the Alabama and Florida populations of the brown pelican have been removed from the federal list due to recent increases in fledgling success. In 2002, taking the Louisiana populations off of the endangered listing is being considered. There are currently 16,4000 nesting pairs and 35,000 young in that state. The Texas population has only 2,400 pairs.

Other problems that face the brown pelican include **habitat** loss, encroachment by humans, and disturbance by humans. Disturbances have included mass visitation of nesting colonies. This practice has been stopped on federally owned lands and access to nesting colonies is restricted. Other human impacts on brown pelican populations have had a more malicious intent. On the California coast in the 1980s there were cases of pelicans' bills being broken purposefully, so that these birds could not feed and would ultimately starve to death. It is thought that disgruntled commercial fishermen faced with dwindling catches were responsible for at least some of these attacks. The brown pelican was a scapegoat for conditions that were due to weather, **pollution**, or, most likely, **overfishing**.

Recovery for the brown pelican has been slow, but progress is being made on both coasts. The banning of DDT in the early 1970s was probably the turning point for this **species**, and the delisting of the Alabama and Florida populations is a hopeful sign for the future.

Brown tree snake

The brown tree snake *(Boiga irregularis)* has caused major ecological and economic damage in Guam, the largest of

the Mariana Islands. The snake is native to New Guinea and northern **Australia**. It has also been introduced to some Pacific islands in addition to Guam.

Brown tree snakes in their natural **habitat** range from 3–6 ft (0.9–1.8 m) in length. Some snakes in Guam are more than 10 ft (3 m) long. The snake's head is bigger than its neck, and its coloring varies with its habitat. In Guam, the snake's brown-and-olive-green pattern blends in with foliage.

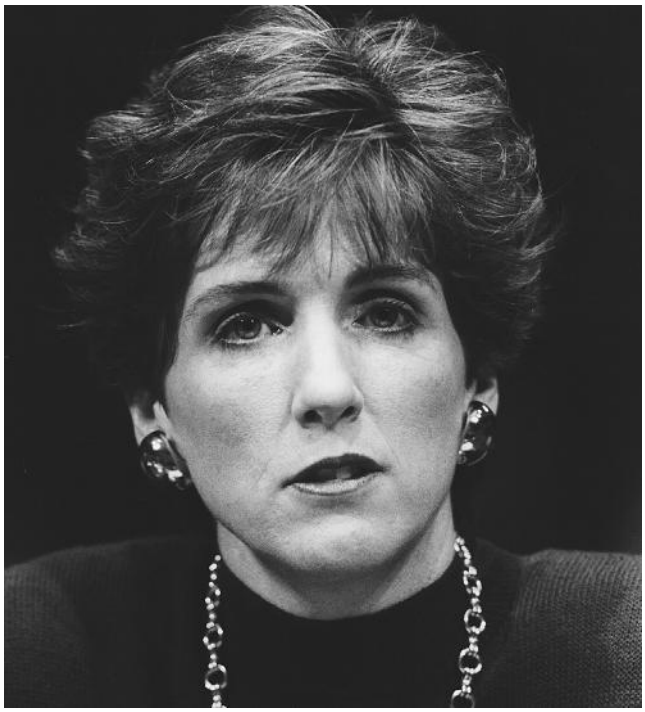
The tree snake was accidentally brought to Guam by cargo ships during the years between the end of World War II (1945) through 1952. On Guam, there were no population controls such as predators that eat snakes. As a result, the snake population boomed. During the late 1990s, there were close to 13,000 snakes per square mile in some areas.

The snake's diet includes birds, and the United States Geographical Survey (USGS) said that the brown tree snake "virtually wiped out" 12 of Guam's native forest birds (three of which are now extinct). Furthermore, snakes crawling on electrical lines caused more than 1,200 power outages from 1978 through 1998.

The USGS and other agencies were working to contain snakes on Guam and stop their spread to Hawaii and other islands.

[*Liz Swain*]

Carol Browner (1955 –)



American former administrator of the Environmental Protection Agency

Carol Browner headed the **Environmental Protection Agency** (EPA) under the Clinton administration. She served from 1993 until 2001, making her the longest-serving director the agency had ever had.

Browner was born in Florida on December 17, 1955. Her father taught English and her mother social science at Miami Dade Community College. Browner grew up hiking in the **Everglades**, where her lifelong love for the natural world began. She was educated at the University of Florida in Gainesville, receiving both a BA in English and her law degree there. Her political career began in 1980 as an aide in the Florida House of Representatives. Browner moved to Washington, D.C. a few years later to join the national office of Citizen Action, a grassroots organization that lobbies for a variety of issues, including the **environment**. She left Citizen Action to work with Florida Senator Lawton Chiles, and in 1989 she joined Senator Al Gore's staff as a senior legislative aide. From 1991 to 1993, Browner headed the Department of Environmental Regulation in Florida, the third-largest environmental agency in the country. She streamlined the process the department used to review permits for expanding manufacturing plants and developing **wetlands**, thus reducing the amount of money and time that process was costing businesses as well as the department. Activists had argued that this kind of streamlining interfered with the ability of government to supervise industries and assess their impact on the environment. But in Florida's business community, Browner built a reputation as a formidable negotiator on behalf of the environment. When the Walt Disney Company filed for state and federal permits to fill in 400 acres of wetlands, she negotiated an agreement which allowed the company to proceed with its development plans in return for a commitment to buy and restore an 8,500-acre ranch near Orlando. She was also the chief negotiator in the settlement of a lawsuit the government had brought against Florida for environmental damage done to Everglades **National Park**. The result was the largest ecological restoration project ever attempted in the United States, a plan to purify and restore the natural flow of water to the Everglades with the cost shared by the state and the federal government, as well as Florida's sugar farmers. Browner was often called "a new type of environmentalist" because of her belief that environmental protection is compatible with economic development and her strong conviction that the stewardship of the environment requires accommodations with industry. "I've found that business leaders don't oppose strong environmental programs," she said in a 1992 interview with the *New York Times*. "What drives them crazy is a lack of certainty."

As director of the EPA, she was determined to protect the environment and public health while not alienating business interests. By many accounts, she was a remarkably successful administrator. She took the job at a time of relatively high environmental fervor, with a Vice President (Al Gore) who had particularly championed the environment, and Democrats in control of both houses of Congress. But a conservative backlash led by Representative Newt Gingrich brought Republican control to the House and Senate in 1994. The political **climate** for environmental reform then became much more embattled. Many conservatives wished to downsize government and cut back the regulatory power of the EPA and other federal agencies. The EPA was shut down twice during Browner's tenure, temporary victim of congressional budgetary squabbles. And appropriations bills for EPA programs were frequently hit with amendments that countermanded the agency's ability to carry out some policies. Despite the hostility of Congress, Browner had several legislative victories. In 1996 Browner led a campaign to have Congress reauthorize the **Safe Drinking Water Act**. That same year she spearheaded the Food Quality Protection Act, which modernized standards that govern **pesticide** use.

Carol Browner. (Corbis-Bettmann. Reproduced by permission.)

This landmark legislation was one of the first environmental laws to specifically protect children's health. The law required scientists to determine what levels of pesticides were safe for children. Browner was also signally successful in getting so-called Superfund sites cleaned up. These were sites that were listed as being particularly polluted. Only 12 Superfund sites had been cleaned up when Browner took over the EPA in 1993. By the time she left the agency, over 700 sites had been cleaned up or were in the process of being cleaned up. After she left the EPA in 2001, Browner continued to work for the environment by becoming a board member of the Audobon Society.

Brownfields

By some estimates, as many as 450,000 urban brownfield sites may exist nationwide. These former commercial or industrial properties can be found in nearly every community where, because of real or perceived contamination, the land sits idle or under-used. Brownfield sites can be as small as a gas station with a **leaking underground storage tank** or as large as a 100-acre (40.5-ha) abandoned factory containing dumped waste on the site. The sites are not remarketed or reused because owners or operators fear that, if the properties are contaminated, the regulatory requirements to clean them up could be prohibitively time-consuming and expensive. Furthermore, even if such properties were put on the market, developers, and financial credit sources would shun them in part from concerns that dealing with contamination cleanup could raise the costs and slow the pace of reusing the properties.

But the brownfields situation has been changing as local, state, and federal government officials recognize the dire need to begin cleaning up and returning these contaminated properties to productive use. These officials point out that reusing the brownfield sites not only would reduce the phenomenon of "urban sprawl" but would also furnish communities with the chance to renew the economic vitality of abandoned urban centers. In many metropolitan areas **urban sprawl** has been recognized as a serious problem, with developers turning to rural greenfields for their projects and thereby reducing **habitat** for **wildlife** and contributing to **air pollution** as commuters drive longer distances to outlying greenfield locations. Moreover, environmental justice advocates point to the need for cleaning up contaminated urban sites to reduce exposure to hazardous contaminants faced by residents in these areas. Together, these factors have created momentum for a national brownfields redevelopment initiative. The promise some see in brownfields redevelopment led the Environmental Manager of Portland, Oregon, to state that "Brownfields renewal is one of the most important environmental and economic challenges facing our nation's communities, calling for partnership among our federal and local governments, business and community and environmental leaders."

Although **land use** decisions are made by local authorities, the U.S. **Environmental Protection Agency** (EPA) plays a critical role in the brownfields **reuse** initiative. On the one hand, the EPA's rules governing contaminated site cleanups, based on federal statutes, have played a significant part in deterring brownfields redevelopment; on the other, the Agency has been a major source of funding for brownfields pilots. In particular, the **Comprehensive Environmental Response, Compensation, and Liability Act** (CERCLA)—commonly known as Superfund—has made

brownfield sites into expensive liabilities, causing businesses to avoid them because stringent cleanup standards and related costs often exceed the property's value. Under CERCLA, new property owners can be held liable for contamination created by previous owners. The **Clean Air Act** also drives businesses away from urban brownfield sites because it burdens companies in areas not attaining national **air quality** standards, making it more attractive for them to locate in rural regions where meeting clean air standards may be easier than in the city.

The EPA began its brownfields pilot program in 1993 by supporting pilot projects—each funded up to $200,000 over two years—at eight separate locations. The goal was to learn about brownfields, which the Agency saw as a new and complex territory in which it had little experience. The EPA awarded its first pilot in November 1993 to Cuyahoga County, Ohio, where the county planning commission had formed a broad effort to involve stakeholders in addressing brownfields reuse. The EPA described Cuyahoga County's report on its brownfields initiative as the most complete known to the Agency on the problems urban areas faced in reusing brownfields. Two additional pilots were awarded in 1994 to Bridgeport, Connecticut, and Richmond, Virginia. By October 1996 the EPA had funded 76 brownfields pilots, 39 under its "National Pilots" selected by the EPA Headquarters in Washington, D.C., and 37 under its "Regional Pilots" selected by the EPA's regional offices. An additional 25 National Pilots were scheduled for selection by March 1997.

In addition to funding pilot projects, the EPA took other actions to underscore its commitment to a Brownfields Economic Redevelopment Initiative, intended to help communities revitalize brownfields properties both environmentally and economically. In January 1995, the EPA Administrator **Carol Browner** announced a Brownfields Action Agenda, stating, "We at EPA firmly believe that environmental cleanup is a building block to economic development, not a stumbling block--that identifying and cleaning up contaminated property must go hand-in-hand with bringing life and vitality back to a community." The Brownfields Action Agenda included the Agency's pilots; joint efforts by EPA, states, and local governments to develop guidance documents to clarify burning liability issues; partnership and outreach endeavors with states, cities, and communities; and job training and development activities, including funding towards an **environmental education** program at Cuyahoga Community College in Cleveland, Ohio.

The National Environmental Justice Advisory Council (NEJAC), chartered in September 1993 as a federal advisory committee to the EPA, in a December 1996 report expressed hope that the Agency's brownfields initiative would stem the "ecologically untenable" and "racially divisive" phenomenon of urban sprawl, in which urban areas were left to stagnate while greenfields were subjected to increasing development. NEJAC also emphasized that the brownfields problem is "inextricably linked to environmental justice" through, for instance, the deterioration of the nation's urban areas. NEJAC reached its hopeful evaluation of the prospects for the brownfields initiative despite misgiving by some NEJAC members that the initiative might be a "smoke screen" for gutting cleanup standards and liability safeguards.

The liability issues addressed under the EPA's Brownfields Action Agenda are among the most important factors affecting these sites. According to the Agency, the fear of inheriting cleanup liabilities for contamination they did not create affects communities, lenders, property owners, municipalities, and others. To help assuage liability concerns, in February 1995 the EPA removed 24,000 of the 40,000 sites listed in its Comprehensive Environmental Response, Compensation and Liability Information System (CERCLIS), a Superfund tracking system. These sites had been screened out of the "Active Investigations" category and designated "No Further Remedial Action Planned," either because they were found to be clean or were being addressed by state cleanup programs. By taking the sites off the CERCLIS list, the EPA hoped to remove any stigma resulting from federal involvement at the sites and thereby to overcome obstacles to their cleanup and reuse.

In May 1995 the EPA issued guidance on "Agreements with Prospective Purchaser of Contaminated Property." The guidance indicated the situations under which the Agency may enter into an agreement to not file a lawsuit against a prospective contaminated property buyer for contamination present at the site before the purchase. Also in May 1995 the EPA issued guidance regarding "Land Use in the CERCLA Remedy Selection Process" to ensure that the Agency considers land use during Superfund cleanups. Land designated for reuse as an industrial site would require less strict cleanup than land designated for a park or school, a recognition that not all contaminated sites should be regarded as equally befouled. In September 1995 the EPA issued guidance that, among other things, released from CERCLA liability governmental units such as municipalities that involuntarily take ownership of property under federal, state, or local law. The EPA hoped this guidance would encourage municipalities to start cleaning up sites without fear of the Superfund liability predicament. These and other guidance documents issued under the Brownfields Action Agenda helped to clarify liabilities facing prospective new owners of private and federally owned contaminated sites.

But the EPA's guidance documents are regarded as only partial solutions to the brownfields problem. A report released February 1997 by the National Association of Local

Government Environmental Professionals (NALGEP), representing 50 cities nationwide, stresses that the EPA's ability to "further clarify and reduce **environmental liability** for brownfields activity is limited," and therefore "legislative solutions" are required to make further progress on the brownfields agenda. Noting that the U.S. House and Senate introduced "numerous brownfields bills" during the 104th Congress and that brownfields legislation is likely in the 105th Congress, NALGEP's report suggests federal law should empower the EPA to delegate authority to the states with cleanup programs that meet minimum requirements to protect health and the **environment**. The EPA would be empowered to authorize qualifying states to limit liability and issue "no action assurances" for less contaminated brownfield sites. Those sites would be clearly differentiated from more seriously contaminated properties that warrant management under the federal Superfund **National Priorities List** of sites.

Going into the 105th Congress, federal lawmakers and President Bill Clinton agreed that brownfields legislation ought to be a priority. Underscoring the close link between brownfields and economic revitalization, Senator Max Baucus (D-Montana), the Ranking Democrat of the Senate Environment and Public Works Committee, said at a press conference in January 1997 that passage of a brownfields bill—apart from Superfund reauthorization legislation—would be a step towards helping create jobs where they are really needed. Welfare reform added to the growing momentum for urban renewal and job opportunities. Representative Michael Oxley (R-Ohio), who proposed Superfund amendments in the 103rd Congress to direct the EPA to help states set up "voluntary cleanup programs" aimed at brownfields sites, compared the federal Superfund liability scheme to the Berlin Wall and said that it should be torn down. The chorus of voices joining Oxley has grown substantially since 1993, and today not only the EPA but also the U.S. Department of Housing and Urban Development, the U.S. Department of Labor, and other federal agencies have joined states and local governments in promoting brownfields redevelopment.

Gro Harlem Brundtland (1939 –)

Norwegian doctor, former Prime Minister of Norway, Director-General of the World Health Organization

Dr. Gro Harlem Brundtland began serving a five-year term as Director-General of the World Health Organization (WHO) in July 1998. A physician and outspoken politician, Gro Harlem Brundtland had been instrumental in promoting political awareness of the importance of environmental issues. In her view, the world shares one economy and one **environment**. With her appointment to the head of WHO, Brundtland continued to work on global strategies to combat ill health and disease.

Brundtland began her political career as Oslo's parliamentary representative in 1977. She became the leader of the Norwegian Labor Party in 1981, when she first became prime minister. At 42, she was the youngest person ever to lead the country and the first woman to do so. She regained the position in 1986 and held it until 1989; in 1990 she was again elected prime minister. Aside from her involvement in the environmental realm, Brundtland promoted equal rights and a larger role in government for women. In her second cabinet, eight of the 18 positions were filled by women; in her 1990 government, nine of 19 ministers were women.

Brundtland earned a degree in medicine from the University of Oslo in 1963 and a master's degree in public health from Harvard in 1965. She served as a medical officer in the Norwegian Directorate of Health and as medical director of the Oslo Board of Health. In 1974 she was appointed Minister of the Environment, a position she held for four years. This appointment came at a time when environmental issues, especially **pollution**, were becoming increasingly important, not only locally but nationally. She gained international attention and in 1983 was selected to chair the United Nation's World Commission on Environment and Development. The commission published ***Our Common Future*** in 1987, calling for sustainable development and intergenerational responsibility as guiding principles for economic growth. The report stated that present economic development depletes both nonrenewable and potentially renewable resources that must be conserved for future generations. The commission strongly warned against environmental degradation and urged nations to reverse this trend. The report led to the organization of the so-called Earth Summit in Rio

Gro Harlem Brundtland. (Corbis-Bettmann. Reproduced by permission.)

de Janeiro in 1992, an international meeting led by the United Nation's Conference on Environment and Development.

Bruntland resigned her position as prime minister in October 1996. This was prompted by a variety of factors, including the death of her son and the possibility of appointment to lead the United Nations. Instead she was picked to head the World Health Organization, an assembly of almost 200 member nations concerned with international health issues. Brundtland immediately reorganized WHO's leadership structure, vowed to bring more women into the group, and called for greater financial disclosure from WHO executives. She began dual campaigns called "Rollback Malaria" and "Stop TB." She also launched an unprecedented campaign to combat **tobacco** use worldwide. Brundtland noted that disease due to tobacco was growing enormously. Tobacco-related illnesses already caused more deaths worldwide than **AIDS** and tuberculosis combined. Much of the growth in smoking was in the developing world, particularly China. Thus in 2000, WHO organized the Framework Convention on Tobacco Control to come up with a world-wide treaty governing tobacco sale, advertising, taxation, and labeling. Brundtland broadened the mission of WHO by attempting the treaty. She was credited with making WHO a more active group, and with making health issues a major component of global economic strategy for organizations such as the United Nations and the so-called G8 group of developed countries. In 2002 Brundtland announced more new goals for WHO, including renewed work on diet and nutrition.

Btu

Abbreviation for "British Thermal Unit," the amount of energy needed to raise the temperature of one pound of water by one degree Fahrenheit. One Btu is equivalent to 1,054 joules or 252 calories. To gain an impression of the size of a Btu, the **combustion** of a barrel of oil yields about 5.6×10^6 joule. A multiple of the Btu, the quad, is commonly used in discussions of national and international energy issues. The term quad is an abbreviation for one quadrillion, or 10^{15}, Btu.

Mikhail I. Budyko (1920 –)

Belarusian geophysicist, climatologist

Professor Mikhail Ivanovich Budyko is regarded as the founder of physical climatology. Born in Gomel in the former Soviet Union, now Belarus, Budyko earned his master of sciences degree in 1942 from the Division of Physics of the Leningrad Polytechnic Institute. As a researcher at the Leningrad Geophysical Observatory, he received his doctorate in physical and mathematical sciences in 1951. Budyko served as deputy director of the Geophysical Observatory until 1954, as director until 1972, and as head of the Division

for Physical Climatology at the observatory from 1972 until 1975. In that year he was appointed director of the Division for Climate Change Research at the State Hydrological Institute in St. Petersburg.

During the 1950s, Budyko pioneered studies on global climate. He calculated the energy or heat balance—the amount of the Sun's radiation that is absorbed by the Earth versus the amount reflected back into space—for various regions of the Earth's surface and compared these with observational data. He found that the heat balance influenced various phenomena including the weather. Budyko's groundbreaking book, *Heat Balance of the Earth's Surface*, published in 1956, transformed climatology from a qualitative into a quantitative physical science. These new physical methods based on heat balance were quickly adopted by climatologists around the world. Budyko directed the compilation of an atlas illustrating the components of the Earth's heat balance. Published in 1963, it remains an important reference work for global climate research.

During the 1960s, scientists were puzzled by geological findings indicating that glaciers once covered much of the planet, even the tropics. Budyko examined a phenomenon called planetary **albedo**, a quantifiable term that describes how much a given geological feature reflects sunlight back into space. Snow and ice reflect heat and have a high albedo. Dark seawater, which absorbs heat, has a low albedo. Land formations are intermediate, varying with type and heat-absorbing vegetation. As snow and ice-cover increase with a global temperature drop, more heat is reflected back, ensuring that the planet becomes colder. This phenomenon is called ice-albedo feedback. Budyko found an underlying instability in ice-albedo feedback, called the snowball Earth or white Earth solution: if a global temperature drop caused ice to extend to within 30 degrees of the equator, the feedback would be unstoppable and the Earth would quickly freeze over. Although Budyko did not believe that this had ever happened, he postulated that a loss of atmospheric **carbon dioxide**, for example if severe **weathering** of silicate rocks sucked up the **carbon** dioxide, coupled with a sun that was 6% dimmer than today, could have resulted in widespread **glaciation**.

Budyko became increasingly interested in the relationships between global climate and organisms and human activities. In *Climate and Life*, published in 1971, he argued that mass extinctions were caused by climatic changes, particularly those resulting from volcanic activity or meteorite collisions with the Earth. These would send clouds of particles into the **stratosphere**, blocking sunlight and lowering global temperatures. In the early 1980s Budyko warned that nuclear war could have a similar effect, precipitating a "nuclear winter" and threatening humans with **extinction**.

By studying the composition of the **atmosphere** during various geological eras, Budyko confirmed that increases in atmospheric carbon dioxide, such as those caused by volcanic activity, were major factors in earlier periods of global warming. In 1972, when many scientists were predicting climate cooling, Budyko announced that fossil fuel consumption was raising the concentration of atmospheric carbon dioxide, which, in turn, was raising average global temperatures. He predicted that the average air temperature, which had been rising since the first half of the twentieth century, might rise another 5°F (3°C) over the next 100 years. Budyko has since been examining the potential effects of global warming on rivers, lakes, and ground water, on twenty-first-century food production, on the geographical distribution of vegetation, and on energy consumption.

The author and editor of numerous articles and books, in 1964 Budyko became a corresponding member of the Division of Earth Sciences of the Academy of Sciences of the Union of Soviet Socialist Republics. In 1992 he was appointed academician in the Division of Oceanology, Atmosphere Physics, and Geography of the Russian Academy of Sciences. His many awards include the Lenin National Prize in 1958, the Gold Medal of the World Meteorological Organization in 1987, the A. P. Vinogradov Prize of the Russian Academy of Sciences in 1989, and the A. A. Grigoryev Prize of the Academy of Sciences in 1995. Budyko was awarded the Robert E. Horton Medal of the American Geophysical Union in 1994, for outstanding contribution to geophysical aspects of **hydrology**. In 1998 Dr. Budyko won the Blue Planet Prize of the Asahi Glass Foundation of Japan.

Buffer

A term in **environmental chemistry** that refers to the capacity of a system to resist chemical change. Most often it is used in reference to the ability to resist change in **pH**. A system that is strongly pH buffered will undergo less change in pH with the addition of an **acid** or a **base** than a less well buffered system. A well buffered lake contains higher concentrations of bicarbonate ions that react with added acid. This kind of lake resists change in pH better than a poorly buffered lake. A highly buffered **soil** contains an abundance of **ion exchange** sites on **clay minerals** and organic matter that react with added acid to inhibit pH reduction. *See also* Acid and base

Bulk density

The mass of **soil** per unit bulk volume. The bulk volume consists of mineral and organic materials, water, and air. Bulk density is affected by external pressures (e.g., weight of tractors and harvesting equipment, mechanical pressures from cultivation machines), and by internal pressures (e.g., swelling and shrinking due to water-content changes, freezing and thawing, and by plant roots). The bulk density of cultivated mineral soils ranges from 1–1.6 mg/m^3.

Burden of proof

The current regulatory system, following traditional legal processes, generally assumes that **chemicals** are innocent, or not harmful, until proven guilty. Thus, the burden to show proof that a chemical is harmful to human and/or **ecosystem health** falls on those who regulate or are affected by these chemicals. As evidence increases that many of the more than 70,000 chemicals in the marketplace today—and the 10,000 more introduced each year—are causing health effects in various **species**, including humans, new regulations are being proposed that would reverse this burden to the manufacturer, importer or user of the chemical and its byproducts. They would then have to prove before its production and distribution that the chemical will not be harmful to human health and the **environment**.

Bureau of Land Management

The Bureau of Land Management (BLM), in the U. S. Department of the Interior, was created by executive reorganization in June 1946. The new agency was a merger of the Grazing Service and the General Land Office (GLO). The GLO was established in the Treasury Department by Congress in 1812 and charged with the administration of the public lands. The agency was transferred to the Department of the Interior when it was established in 1849. Throughout the 1800s and early 1900s, the GLO played the central role in administering the disposal of public lands under a multitude of different laws. But, as the nation began to move from disposal of public lands to retention of them, the services of the GLO became less needed, which helped to pave the way for the creation of the BLM. The Grazing Service was created in 1934 (as the Division of Grazing) to administer the **Taylor Grazing Act**.

In the 1960s, the BLM began to advocate for an organic act that would give it firmer institutional footing, would declare that the federal government planned to retain the BLM lands, and would grant the agency statutory authority to professionally manage these lands (like the **Forest Service**). Each of these goals was achieved with the passage of the **Federal Land Policy and Management Act** (FLPMA) in 1976. The agency was directed to manage these lands and undertake long-term planning for the use of the lands, guided by the principle of multiple use.

The BLM manages 272 million acres (110 million ha) of land, primarily in the western states. This land is of three types: Alaskan lands (92 million acres; 37.2 million ha), which is virtually unmanaged; the Oregon and California lands (2.6 million acres; 1 million ha), prime timber land in western Oregon that reverted back to the government in the early 1900s due to land grant violations; and the remaining land (177 million acres; 71.8 million ha), approximately 70% of which is in grazing districts. As a multiple use agency, the BLM manages these lands for a number of uses: fish and **wildlife**, forage, minerals, **recreation**, and timber. Additionally, FLPMA directed that the BLM review all of its lands for potential **wilderness** designation, a process that is now well underway. (BLM lands were not covered by the **Wilderness Act** of 1964). In addition to these general land management responsibilities, the BLM also issues leases for mineral development on all public lands. FLPMA also directed that all mineral claims under the 1872 Mining Law be recorded with the BLM.

The BLM is headed by a director, appointed by the President, and confirmed by the Senate. The chain of command runs from the Director in Washington to state directors in 12 western states (all but Hawaii and Washington), to district managers, who administer grazing or other dis-

tricts, to resource area managers, who administer parts of the districts.

The BLM has often been compared unfavorably to the Forest Service. It has received less funding and less staff than its sibling agency, has been less professional, and has been characterized as captured by livestock and mining interests. Recent studies suggest that the administrative capacity of the BLM has improved.

Bureau of Oceans and International Environmental and Scientific Affairs (OES)

The Bureau of OES was established in 1974 under Section 9 of the Department of State Appropriations Act. It is the lead office in Department of State in the formulation of foreign policy in four areas: 1) International Science and Technology (S&T) Affairs; 2) Environmental, Health, Natural Resource Protection and Global **Climate** Change; 3) Nuclear Energy and Energy Technology Affairs; and 4) Oceans and Fisheries Affairs. Each area is headed by a Deputy Associate Secretary of State. A Bureau coordinator oversees the Office of World Population Affairs. OES provides support and guidance to U. S. Embassy science counselors and attaches in reporting and negotiations. It has responsibility for the International Fisheries Commissions, the Fisherman's Guarantee Fund and the U.S. Secretariat for the **Man and the Biosphere Program**. The bureau prepares an annual Presidential report (the title V Report) on international "Science, Technology and American Foreign Policy.

Bureau of Reclamation

The U. S. Bureau of **Reclamation** was established in 1902 and is part of the U. S. Department of the Interior. It is primarily responsible for the planning and development of **dams**, **power plants**, and water transfer projects, such as Grand Coulee Dam on the Columbia River, the Central Arizona Project, and Hoover Dam on the **Colorado River**. This latter dam, completed in 1935 between Arizona and Nevada, is the highest arch dam in the Western Hemisphere and is part of the Boulder Canyon Project, the first great multipurpose water development project, providing **irrigation**, electric power, and flood control. It also created Lake Mead, which is supervised by the **National Park Service** to manage boating, swimming, and camping facilities on the 115 mi-long (185-km-long) **reservoir** formed by the dam. The dams on the Colorado River are intended to reduce the impact of the destructive cycle of floods and droughts which makes settlement and farming precarious and to provide electricity and recreational areas; however, the deep canyons and free-flowing rivers with their attendant ecosystems are substantially altered. Along the Columbia River, efforts are made to provide "fish ladders" adjacent to dams to enable **salmon** and other **species** to bypass the dams and spawn up river; however, these efforts have not been as successful as desired and many native species are now endangered.

Problems faced by the Bureau relate to creating a balance between its mandate to provide hydropower, water control for irrigation, and by-product **recreation** areas, and the conflicting need to preserve existing ecosystems. For example, at the **Glen Canyon Dam** on the Colorado River, controls on water releases are being imposed while studies are completed on the best manner of protecting the **environment** downstream in the Grand Canyon **National Park** and the Lake Mead National Recreation Area.

Buried soil

Buried **soil** is soil that appeared on the surface of the earth and sustained plant life but because of a geologic event has been covered by a layer of **sediment**. Sediments can result from volcanoes, rivers, dust storms, or blowing sand or **silt**.

John Burroughs (left) with naturalist John Muir. (Corbis-Bettmann. Reproduced by permission.)

John Burroughs (1837 – 1921)

American naturalist and writer

A follower of both **Henry David Thoreau** and Ralph Waldo Emerson, Burroughs more clearly defined the **nature** essay as a literary form. His writings provided vivid descriptions of outdoor life and gained popularity among a diverse audience.

Burroughs spent his boyhood exploring the lush countryside surrounding his family's dairy farm in the valleys of the Catskill Mountains, near Roxbury, New York. He left school at age sixteen and taught grammar school in the area until 1863, when he left for Washington, D.C., for a position as a clerk in the U. S. Treasury Department. While in Washington, Burroughs met poet Walt Whitman, through whom he began to develop and refine his writing style. His early essays were featured in the *Atlantic Monthly*. These works, including "With the Birds" and "In the Hemlocks," detailed Borroughs's boyhood recollections as well as recent observations of nature. In 1867 Burroughs published his first book, *Notes on Walt Whitman as a Poet and Person*, to which Whitman himself contributed significantly. Four years later, Burroughs produced *Wake-Robin* independently, followed by *Winter Sunshine* in 1875, both of which solidified his literary reputation.

By the late 1800s, Burroughs had returned to New York and built a one-room log cabin house he called "Slabsides," where he philosophized with such guests as **John Muir**, **Theodore Roosevelt**, Thomas Edison, and Henry Ford. Burroughs accompanied Roosevelt on many adventurous expeditions and chronicled the events in his book, *Camping and Tramping with Roosevelt* (1907).

Burroughs's later writings took new directions. His essays became less purely naturalistic and more philosophical and deductive. He often sought to reach the levels of spirituality and vision he found in the works of Whitman, Emerson, and Thoreau. Borroughs explored poetry, for example, in *Bird and Bough* (1906), and *The Summit of the Years* (1913), which searched for a less scientific explanation of life, while *Under the Apple Trees* (1916) examined World War I.

Although Burroughs's enthusiastic inquisitiveness prompted travel abroad, he traveled primarily within the United States. He died in 1921 enroute from California to his home in New York. Following his death, the John

Burroughs Association was established through the auspices of the American Museum of Natural History. The association remains active and continues to maintain an exhibit at the museum.

Bush meat/market

Humans have always hunted wild animals for food, commonly known as bush meat. For many people living in the forests of Africa, South America, and Southeast Asia, **hunting** remains a way of life. However during the 1990s bush meat harvesting, particularly in Africa, was transformed from a local subsistence activity into a profitable commercial enterprise. In 2001, the United Nations Food and Agriculture Organization (FAO) warned that over-hunting in many parts of the world threatened the survival of some animal **species** and the food security of human forest-dwellers.

Although the killing of **endangered species** is illegal, such laws are rarely enforced across much of Africa. Bush meat harvesting is threatening the survival of **chimpanzees** (*Pan troglodytes*), gorillas (*Gorilla gorilla*), and bonobos (pygmy chimps) (*P. paniscus*), as well as some species of smaller monkeys and duikers (small antelope). Colobus monkeys and baboons, including drills and mandrills, are highly-prized as bush meat. In 2000, Miss Waldron's red colobus monkey (*Procolobus badius waldroni*) was declared extinct from over-hunting. Protected **elephants** and wild boar, gazelle, impala, crocodile, lizards, insects, **bats**, birds, snails, porcupine, and squirrel are all killed for bush meat. The chameleons and radiated tortoises of **Madagascar** are threatened with **extinction** from over-hunting.

In Indonesia and Malaysia, particularly on Borneo, orangutans (*Pongo pygmaeus*) are hunted despite their full legal protection. In Southeast Asia, freshwater turtles, harvested for food and medicine, are critically endangered.

Large animals and those that travel in groups are easy targets for hunters whose traditional spears, snares, and nets have been replaced with shotguns and even semi-automatic weapons. Since large animals reproduce slowly, the FAO is encouraging the hunting of smaller animals whose populations are more likely to be able to sustain the harvesting.

With populations of buffalo and other popular African game declining, hunters are beginning to stalk animals such as zebra and hippo that had been protected by local custom and taboos. Hunters also are turning to rodents and reptiles—animals that were previously shunned as food. Local customs against hunting bonobos are collapsing as more humans move into bonobo **habitat**.

Logging in the Congo Basin, the world's second-largest tropical forest, has contributed to the dramatic rise in bush meat harvesting. Logging companies are bringing thousands of workers into sparsely populated areas and feeding them with bush meat. Logging roads open up new areas to hunters and logging trucks carry bush meat to market and into neighboring countries. It has been estimated that about 2,000 bush meat hunters, supported by the logging industry, will kill more than 3,000 gorillas and 4,000 chimpanzees in 2002. Mining and wars also contribute to the increased harvesting of bush meat. Conservationists warn that by 2012 the large mammals of the Congo Basin will be gone.

The expanding market for African bush meat is fueled by human **population growth** and increasing poverty. In rural areas and among the poor, bush meat is often the only source of meat protein, particularly in times of **drought** or **famine**. It also may be the only source of cash income for the rural impoverished. With the urbanization of Africa, the taste for bush meat has moved to the cities. Bush meat is readily available in urban markets, where it is considered superior to domesticated meat. Primate meat is sold fresh, smoked, or dried. Bush meat is on restaurant menus throughout Africa and Europe. Monkey meat is smuggled into the United Kingdom where it is surreptitiously sold in butcher shops. It has been estimated that over one million tons of bush meat is harvested in the Congo Basin every year and that the bush meat trade in central and western Africa is worth more than one billion dollars annually.

Primate meat may contain viruses that are responsible for several emerging human diseases. Scientists believe that humans can contract the deadly **Ebola virus** from infected chimpanzees and gorillas. Furthermore, killing and dressing chimpanzee meat in the wild may contribute to the spread of the human immunodeficiency virus (HIV) that causes **AIDS**.

The Bushmeat Crisis Task Force (BCTF) is working with logging companies in the Congo Basin and West Africa to prevent illegal hunting and the use of company roads for the bush meat trade. The BCTF also works with governments and local communities to develop investment and foreign-aid policies that promote **sustainable development** and **wildlife** protection. Other organizations try to turn hunters into conservationists and educate bush meat

consumers. TRAFFIC, which monitors wildlife trade for the **World Wildlife Fund**, and the World Conservation Union are urging that wildlife ownership be transferred from ineffectual African governments to landowners and local communities who have a vested interest in sustaining wildlife populations.

BWCA

see **Boundary Waters Canoe Area**

Bycatch

The use of certain kinds of **commercial fishing** technologies can result in large bycatches—incidental catches of unwanted fish, **sea turtles**, seabirds, and marine mammals. Because the bycatch animals have little or no economic value, they are usually jettisoned, generally dead, back into the ocean. This non-selectivity of commercial fishing is an especially important problem when trawls, seines, and drift nets are used. The bycatch consists of unwanted **species** of fish and other animals, but it can also include large amounts of undersized, immature individuals of commercially important species of fish.

The global amount of bycatch has been estimated in recent years at about 30 billion tons (27 million tonnes), or more than 1/4 of the overall catch of the world's fisheries. In waters of the United States, the amount of unintentional bycatch of marine life is about 2.2 billion lb per year (1 billion kg per year). However, the bycatch rates vary greatly among fisheries. In the fishery for cod and other groundfish species in the North Sea, the discarded non-market **biomass** averages about 42% of the total catch, and it is 44–72% in the Mediterranean fishery. Discard rates are up to 80% of the catch weight for trawl fisheries for shrimp.

Some fishing practices result in large bycatches of sea turtles, marine mammals, and seabirds. During the fishing year of 1988–1989, for example, the use of pelagic drift nets, each as long as 90 km, may have killed as many as 0.3-1.0 million **dolphins**, porpoises, and other cetaceans. During one 24-day monitoring period, a typical set of a drift-net of 19 km/day in the Caroline Islands of the south Pacific entangled 97 dolphins, 11 larger cetaceans, and 10 sea turtles. It is thought that bycatch-related **mortality** is causing population declines in 13 out of the 44 species of marine mammals that are suffering high death rates from human activities. It is also believed that hundreds of thousands of seabirds have been drowned each year by entanglement in pelagic drift-nets.

In 1991, the United Nations passed a resolution that established a moratorium on the use of drift-nets longer than 1.6 mi (2 km), and most fishing nations have met this guideline. However, there is still some continued use of large-scale drift nets. Moreover, the shorter nets that are still legal are continuing to cause extensive and severe bycatch mortality.

Sea turtles, many of which are federally listed as endangered, appear to be particularly vulnerable to being caught and drowned in the large, funnel-shaped trawl nets used to catch shrimp. Scientists have, however, designed simple, selective, **turtle excluder devices** (TEDs) that can be installed on the nets to allow these animals to escape if caught.

The use of TEDs is required in the United States and many other countries, but not by all of the fishing nations.

Purse seining for tuna has also caused an enormous mortality of certain species of dolphins and porpoises. This method of fishing is thought to have killed more than 200-thousand small cetaceans per year since the 1960s, but perhaps about one-half that number since the early 1990s due to improved methods of deployment used in some regions. Purse seining is thought to have severely depleted some populations of marine mammals.

The use of long-lines also results in enormous bycatches of various species of large fishes, such as tuna, **swordfish**, and **sharks**, and it also kills many seabirds. Long-lines consist of a fishing line up to 80 mi (130 km) long and baited with thousands of hooks. A study in the Southern Ocean reported that more than 44,000 albatrosses of various species are killed annually by long-line fishing for tuna.

In addition, great lengths of fishing nets are lost each year during storms and other accidents. Because the synthetic materials used to manufacture the nets are extremely resistant to degradation, these so-called "ghost nets" continue to catch and kill fish and other marine mammals for many years.

Clearly, fishery bycatches can cause substantial, non-target mortality that is a grave threat to numerous marine species. It is urgent that effective action be taken to curtail this wasteful environmental impact of commercial fishing as soon as possible.

Bycatch reduction devices

Seabirds, **seals**, **whales**, **sea turtles**, **dolphins**, and non-targeted fish can be unintentionally caught and killed or maimed by modern fish and shrimp catching methods. This phenomenon is called "bycatch" or the unintended capture or **mortality** of living marine resources as a result of fishing. It is managed under such laws as the Migratory Bird Treaty Act, the **Endangered Species Act** of 1973, the **Marine Mammals Protection Act** of 1972 (amended in 1994), and, most recently, the Magnuson-Stevens Fishery Conservation and Management Act of 1996. The 1995 United Nations Code of Conduct for Responsible Fisheries, to which the United States is a signatory, also emphasizes the importance of **bycatch** reduction. Bycatch occurs because most fishing methods are not perfectly "selective," (i.e., they do not catch and retain only the desired size, sex, quality and quantity of **target species**). It also occurs because fishermen often have incentive to catch more fish than they will keep.

Although the exact extent of bycatch-related mortality is uncertain, public awareness of the problem has grown in the 1990s, leading to a deepening public perception that commercial fisheries are wasteful of the world's finite marine resources. According to a 1994 estimate of the United Nations' Food and Agriculture Organization, worldwide **commercial fishing** operations discarded 30 million tons (27 million metric tons) of fish, approximately one-fourth of the world catch, because they were the wrong type, sex, or size. In United States fisheries, a total of 149 **species** groups have been identified as bycatch, 67% of them finfish, crustaceans, or mollusks, and 37% of them protected marine mammals, turtles, or seabirds.

To address this problem, numerous research programs have been established to develop BRDs and other means to reduce bycatch. Much of this research, and the nation's bycatch reduction activities overall, is centered in the Department of Commerce's National Marine Fisheries Service (NMFS), which leads and coordinates the United States' collaborative efforts to reduce bycatch. In March 1997, NMFS proposed a draft long-term strategy, *Managing the Nation's Bycatch*, that seeks to provide structure to the service's diverse bycatch-related research and management programs. These include gear research, technology transfer workshops, and the exploration of new management techniques. NMFS's Bycatch Plan was intended to as a guide for its own programs and for its "cooperators" in bycatch reduction, including eight regional fishery management councils, states, three interstate fisheries commissions, the fishing industry, the conservation community, and other parties. In pursuing its mandate of conserving and managing marine resources, NMFS relies on the direction for bycatch established by the 104th Congress under the new National

Standard 9 of the Magnuson-Stevens Act, which states: "Conservation and management measures shall, to the extent practicable, (A) minimize bycatch and (B) to the extent bycatch cannot be avoided, minimize the mortality of such bycatch."

But, although the national bycatch standard applies across all regions, bycatch issues are not uniform for all fisheries. Indeed, bycatch is not always a problem and can sometimes be beneficial, (e.g., when bycatch species are kept and used as if they had been targeted species). But where bycatch is a problem, the exact nature of the problem and potential solutions will differ depending on the region and fishery. For instance, in the U.S. Gulf of Mexico shrimp fishery, which contributes about 70% of the annual U.S. domestic shrimp production, bycatch of juvenile red snapper (*Lutjanus blackfordi*) by shrimp trawlers reduces red snapper stocks for fishermen who target those fish. According to NMFS, "In the absence of bycatch reduction, red snapper catches will continue to be a fraction of maximum economic or biological yield levels." To address this problem, the Gulf of Mexico Fishery Management Council prepared an amendment to the shrimp fishery management plan for the Gulf of Mexico requiring shrimpers to use BRDs in their nets. But BRD effectiveness differs, and devices often lose significant amounts of shrimp in reducing bycatch. For instance, one device called a "30-mesh fisheye" reduced overall shrimp catches, and revenues, by 3%, an issue that must be addressed in any analysis of the costs and benefits of requiring BRDs, according to NMFS. In Southern New England, the yellowtail flounder (*Pleuronectes ferrugineus*) has been important to the New England groundfish fisheries for several decades. But the stock has been depleted to a record low because, from 1988–1994, most of the catch has been discarded by trawlers. Reasons for treating the catch as bycatch were that most of the fish were either too small for marketing or were smaller than the legal size limit. Among the solutions to this complex problem an increase in the mesh size of nets so smaller fish would not be caught and a redesign of nets to facilitate the escape of undersized yellowtail flounder and other bycatch species.

Although fish bycatch exceeds that of other marine animals, it is by no means the only significant bycatch problem. Sea turtle bycatch has received growing attention in recent years, most notably under the **Endangered Species** Act Amendments of 1988, which mandated a study of sea turtle conservation and the causes and significance of their mortality, including mortality caused by commercial trawlers. That study, conducted by the **National Research Council** (NRC), found that shrimp trawls accounted for more deaths of sea turtle juveniles, subadults, and breeders in coastal waters than all other human activities combined. According to the NRC's 1990 report, some 5,000–50,000 loggerhead turtles (*Caretta caretta*) and 500–5,000 Kemp ridleys (*Lepidochelys kempi*) a year are killed by shrimping operations from Cape Hatteras, North Carolina, to the Mexican border in the Gulf of Mexico. Deaths from drowning increase when trawlers tow their catch for longer than 60 minutes. Winter flounder trawling north of Cape Hatteras, **Chesapeake Bay** passive-gear fishing, and other fisheries were also found to be responsible for some turtle mortality.

To address the turtle bycatch problem, NMFS, numerous Sea Grant programs, and the shrimping industry conducted research that led to the development of several types of net installation devices that were called "turtle excluder devices" (TEDs) or "trawler efficiency devices." In 1983, the only TED approved by NMFS was one developed by the service itself. But in the face of industry concerns about using TEDs, the University of Georgia and NMFS tested devices developed by the shrimping industry, resulting in NMFS certification of new TED designs. Each design was intended to divert turtles out of shrimp nets, excluding the turtles from the catch without reducing the shrimp intake. Over a decade of development, these devices have been made lighter and today at least six kinds of TEDs have NMFS's approval. Early in the development of TEDs, NMFS tried to obtain voluntary use of the devices, but shrimpers considered them an expensive, time-consuming nuisance and feared they could reduce the size of shrimp catches. But NMFS, and environmental groups, countered that the best TEDs reduced turtle bycatch by up to 97% with slight or no loss of shrimp. By 1985, NMFS faced threats of lawsuits to shut down the shrimping industry because trawlers were not using TEDs. In response, NMFS convened mediation meetings that included environmentalists and shrimpers. The meetings led to an agreement to pursue a "negotiated rulemaking" to phase in mandatory TED use, but negotiations fell apart after state and federal legislators, under intense pressure, tried to delay implementation of TED rules. After intense controversy, NMFS published regulations June 28, 1987, on the use of TEDs by shrimp trawlers.

Dolphins are another marine animal that has suffered significant mortality levels as a result of bycatch associated with the eastern tropical Pacific Ocean tuna fishery. Several species of tuna are often found together with the most economically important tuna species, the yellowfin (*Thunnus albacares*). As a result, tuna fishermen have used a fishing technique--called "dolphin fishing," in which they set their nets around herds of dolphins to capture the tuna that are always close by. The spotted dolphin (*Stenella attenuata*) is most frequently associated with tuna. Spinner dolphin (*Stenella longirostris*), and the common dolphin (*Delphinus delphis*) also travel with tuna. According to one estimate, between 1960–1972 the U.S. fleet in the eastern tropical

Pacific Ocean fishery killed more than 100,000 dolphins a year. That number dropped to an estimated 20,000 after 1972, when the Marine Mammals Protection Act was passed. By 1989, the number was estimated at 12,643, largely because the number of boats in the U.S. tuna fishing fleet declined and those that were in operation killed fewer dolphins. U.S. fishing boats are now required to use techniques that allow dolphins to escape from tuna nets before the catch is hauled in. These include having fishermen jump into the ocean to hold the lip of the net below the water surface so the dolphin can jump out.

C

Cadmium

A metallic element that occurs most commonly in **nature** as the sulfide, CdS. Cadmium has many important industrial applications. It is used to electroplate other metals, in the production of paints and **plastics**, and in nickel-cadmium batteries. The metal also escapes into the **environment** during the burning of **coal** and **tobacco**. Cadmium is ubiquitous in the environment, with detectable amounts present in nearly all water, air, and food samples. In high doses, cadmium is toxic. In lower doses, it may cause kidney disease, disorders of the circulatory system, weakening of bones, and, possibly, **cancer**. *See also* Itai-Itai disease

Cairo conference

The 1994 International Conference on Population and Development occurs at a defining moment in the history of international cooperation, the preamble to the Program of Action for the United Nations International Conference on Population and Development (UN ICPD) stated. This historic conference, the fifth such world meeting regarding population issues, was held in Cairo, Egypt September 5th to 13th, 1994, at a time when there was growing, worldwide recognition of the interdependence between global population, development and **environment**. The Cairo Conference considered itself as building upon the foundation already laid in the 1974 World Population Conference in Bucharest and the 1984 International Conference on Population in Mexico City.

Representatives from 180 countries throughout the world gathered to discuss these problems. In order to represent particular world societal blocs, the UN ensured representation from four communities of nations: developing countries, Muslim states, the industrialized West, and Catholic countries. The makeup of attending blocs was intentional, as controlling the world's population involves many hotly debated issues that bring about sharp differences of opinion on religious and cultural beliefs. Conference attendees and those that would follow up on the conference's recommendations in their host nations would have to address issues like marriage, divorce, abortion, contraception and homosexuality.

The call to address **population growth** came at a time when some groups said that the world was already pushing its food supply to natural limits. For example, marine biologists stated that ocean fisheries could not sustain catches upwards of 100 million tons of fish per year. Yet, that level was reached in 1989. Seafood prices have continued to rise since that time but seafood production has continued and so has population growth. In many countries, underground water supplies are reportedly strained and farming has been exploited to its capacity. The world population was estimated that year at 5.6 billion people, and projected to continue to increase at the 1994 level of 86 million people per year. Most frightening of all were the United Nations population projections for the twenty years to follow. These estimates ranged between 7.9 billion to 11.9 billion people inhabiting the earth by 2014.

In his opening address on September 5, UN Secretary-General Boutros-Boutros-Ghali said, **The efficacy of the economic order of the planet on which we live depended in great measure on the conference's outcome.**. Leaders of several countries spoke of the many issues surrounding the problem and causing social and ethical dilemmas in setting population policy. Vice-President Albert Gore of the United States spoke of a **holistic** approach that also comprehensively addresses world poverty. Over the course of six days, more than 200 speakers shared their concerns about population and strategies to curb growth. Because the conference was mandated to address the issues and how they impacted population, the debate branched out to a number

of economic, reproductive, trade, environmental, family structure, healthcare, and education issues.

The following areas of need were spelled out in the UN ICPD **Programme of Action**:

- Rapid urbanization and movement within and across borders are additional population problems the Cairo conference attempted to address. At that time, more than 93 percent of the 93 million people added to the population each year lived in developing countries. UN data just prior to the conference also showed that 43 percent of the world population resided in urban areas, up from 38 percent in 1975.
- The conference's delegates agreed on common objectives for controlling the world's population and even took on a more ambitious goal of population growth limit than anticipated by some. The conference objectives are targeted for completion by the year 2015. The common strategy limits family size and helps empower women to participate in reproductive decisions.
- The Cairo conference goals also addressed some **mortality** issues, and set an objective of reducing infant mortality worldwide by 45%. In 1994, infant mortality averaged 62 per 1,000 live births. The conference's objective aimed to lower that number to only 12 per 1,000 live births.
- A goal was also outlined to lower maternal mortality to 30 per 100,000 women. These objectives would be furthered by a pledge to offer prenatal care to all pregnant women.
- The conference also included an objective addressing education. It outlined that all children of school age be enabled to complete primary education.
- Contraception availability became another tool to limit population growth. The delegates settled on a goal of making contraception accessible to 70% of the world's population by the year 2015. However, they also added universal access to **family planning** as a final objective.
- In order to meet family planning goals, some leaders in the field suggested a shift in how leaders looked at their policies. Prior to the conference, they tended to focus on organized family planning programs. The Cairo conference objectives shifted the focus to a broadened policy, concerned with issues like gender equality, education, and empowerment of women to better deal with reproductive choices.
- The aging of the populations in more developed countries was also discussed.

Although unprecedented agreement was reached over the few days in Cairo, it didn't happen without heated debate and controversy. Most participants supported the notion that population policies must be based on individual rights and freedom of choice, as well as the rights of women and cultures. Since abortion was considered such a sensitive issue, many delegates agreed that family planning offered women alternative recourse to abortion. The Cairo Conference ended with both hope and concern for the future. If the conference objectives were reached, the delegates projected that world population would rise from 5.7 billion in the mid-1990s to 7.5 billion by the year 2015, and then begin to stabilize. However, if the objectives were not reached, conference attendees concluded that the population would continue to rise to the perilous numbers discussed in the conferences preamble.

Following the Cairo conference, the United States began implementing the conference objectives. The U.S. Agency for International Development (USAID) held a series of meetings between September 1994 and January 1995 to draw upon the expertise and ideas of American leaders in the field and to begin encouraging U.S. participation in population control goals. Among the USAID's own objectives for the United States were new initiatives and expansion of programs in place that emphasized family planning and health, as well as education and empowerment of women in America. For example, USAID suggested expanding access to reproductive health information and services and improved prevention of HIV/AIDS and other sexually transmitted diseases (STDs). It also promoted research on male methods of contraception and new barrier methods to protect from both pregnancy and STDs. The agency focused on improving women's equality and rights beginning with review of existing U.S. programs. A major focus would also include improving women's economic equity in the United States.

Such initiatives cost money. The U.S. Congress appropriated $527 million to family planning and reproductive health in fiscal year 1995 alone. A number of additional programs received substantial funding to support the economic, social, and educational programs needed to complete the United States' objectives related to the Cairo conference. Included in this overall program was establishment of the President's Council on **Sustainable Development**, a combination public/private group charged with making recommendations on U.S. policies and programs that will help balance population growth with consumption of **natural resources**. The United States also worked cooperatively with Japan prior to and following the conference on a common agenda to coordinate population and health assistance goals. The program also was designed to help strengthen relations between Japan and the United States.

Five years after the Cairo conference, a follow-up conference was held in New York City from June 30th to July 2nd, 1999. In preparation for the conference, a forum was held at The Hague, Netherlands. At that forum, delegates of several countries that had expressed concerns about the

Cairo conference objectives five years earlier began trying to renegotiate the program of action. By the time the **Cairo Plus Five** conference convened in 1999, final recommendations had not been completed, as some member delegates, including representatives of the Vatican in Rome, attempted to alter the original Cairo program of action. Money was yet another issue in focus at the 1999 meeting. United Nations Population Fund (UNPFA) Chief Nafis Sadik estimated that $5.7 billion per year was needed to meet the Cairo Conference aims, an amount she described as **peanuts**. The actual average amount available to the **Programme of Action** was far less, $2.2 billion.

The real measure of success lies in whether or not world population stabilizes. There is some evidence to suggest that while still growing, the number of human beings inhabiting this planet is not growing at the nightmare rates projected at the beginning of the Cairo Conference. The United States Bureau of Census projections, revised in 1999, now estimate a world population of 8 billion by 2024, approximately the lowest estimate the Cairo Conference projected for 2014.

Calcareous soil

A calcareous **soil** is soil that has calcium carbonate ($CaCO_3$) in abundance. If a calcareous soil has hydrochloric **acid** added to it, the soil will effervesce and give off **carbon dioxide** and form bubbles because of the chemical reaction. Calcareous soils are most often formed from limestone or in dry environments where low rainfall prevents the soils from being leached of carbonates. Calcareous soils frequently cause **nutrient** deficiencies for many plants.

Dr. Helen Mary Caldicott (1938 –)

Australian physician and activist

Dr. Helen Caldicott is a pediatrician, mother, antinuclear activist, and environmental activist. Born Helen Broinowski in Melbourne, **Australia** on August 7, 1938, she is known as a gifted orator and a tireless public speaker and educator. She traces her activism to age 14 when she read Nevil Shute's *On the Beach*, a chilling novel about nuclear holocaust. In 1961 she graduated from the University of Adelaide Medical School with bachelor of medicine and bachelor of surgery degrees, which are the equivalent of an American M.D. She married Dr. William Caldicott in 1962, and returned to Adelaide, Australia to go into general medical practice. In 1966 she, her husband, and their three children moved to Boston, Massachusetts, where she held a fellowship at Harvard Medical School. Returning to Australia in 1969, she served first as a resident in pediatrics and then as an intern in pediatrics at Queen Elizabeth Hospital. There, she set up a clinic for cystic **fibrosis**, a genetic disease in children.

In the early 1970s, Caldicott led a successful campaign in Australia to ban atmospheric nuclear testing by the French in the South Pacific. Her success in inspiring a popular movement to stop the French testing has been attributed to her willingness to reach out to the Australian people through letters and television and radio appearances, in which she explained the dangers of **radioactive fallout**. Next, she led a successful campaign to ban the exportation of **uranium** by Australia. During that campaign she met strong **resistance** from Australia's government, which had responded to the 1974 international **oil embargo** by offering to sell uranium on the world market. (Uranium is the raw material for nuclear technology.) Caldicott chose to go directly to mine workers, explaining the effects of radiation on their bodies and their genes and talking about the effects of nuclear war on them and their children. As a result, the Australian Council of Trade Unions passed a resolution not to mine, sell, or transport uranium. A ban was instituted from 1975 to 1982, when Australia gave in to international pressure to resume the exportation.

In 1977 Dr. Caldicott and her husband immigrated to the United States, accepting appointments at the Children's Hospital Medical Center and teaching appointments at Harvard Medical School in Boston, Massachusetts. She was a co-founder of Physicians for Social Responsibility (PSR), and she was its president at the time of the March 28, 1979 nuclear accident at the **Three Mile Island Nuclear Reactor** in Pennsylvania. At that time, PSR was a small group of concerned medical specialists. Following the accident, the organization grew rapidly in membership, financial support, and influence. As a result of her television appearances and statements to the media following the Three Mile Island

accident, Caldicott became a symbol of the movement to ban all **nuclear power** and oppose **nuclear weapons** in any form. Ironically, she resigned as president of PSR in 1983, when the organization had grown to over 20,000 members. At that time, she began to be viewed as an extreme radical in an organization that had become more moderate as it came to represent a wide, diversified membership.

She also founded Women's Action for Nuclear Disarmament (WAND). WAND has been an effective group lobbying Congress against nuclear weapons.

Throughout her career, Caldicott has considered her family to be her first priority. She has three children and she emphasizes the importance of building and maintaining a strong marriage, believing that good interpersonal relationships are essential before a socially-minded person can work effectively for broad social change.

Caldicott has developed videotapes and films and has written over one hundred articles which have appeared in major newspapers and magazines throughout the world. She has written four books. Her first, *Nuclear Madness: What You Can Do* (1978) is considered important reading in the antinuclear movement. Her second, entitled *Missile Envy*, was published in 1986. In *If You Love This Planet: A Plan to Heal the Earth* (1992), Caldicott discusses the race to save the planet from environmental damage resulting from excess energy consumption, **pollution**, **ozone layer depletion**, and global warming. She urges citizens of the United States to follow the example set by the Australians, who have adopted policies and laws designed to move their society toward greater corporate and institutional responsibility. She urges the various nations of the world to strive for a "new legal world order" by moving toward a sort of transnational control of the world's **natural resources**. One of her books, *A Desperate Passion*, (1996) is an autobiography in which she reflects upon crucial events that have influenced her and talks about people who have inspired her in her life and work. Her latest work was entitled *The New Nuclear Danger: George Bush's Military Industrial Complex* (2002).

Caldicott is the recipient of many awards and prizes including the SANE Peace Prize, the Ghandi Peace Prize, the John-Roger Foundation's Integrity Award (which she shared with Bishop Desmond Tutu), the Norman Cousins Award for Peace-making, the Margaret Mead Award, and many others.

Lynton Keith Caldwell (1913 –)

American scholar and environmentalist

Lynton Caldwell has been a key figure in the development of **environmental policy** in the United States. A longtime advocate for adding an environmental amendment to the Constitution, Caldwell has insisted that the federal government has a duty to protect the **environment** that is akin to the defense of civil rights or freedom of speech.

Caldwell was born November 21, 1913 in Montezuma, Iowa. He received his bachelor of arts from the University of Chicago in 1935 and completed a master of arts at Harvard University in 1938. The same year, Caldwell accepted an assistant professorship in government at Indiana University in Bloomington. In 1943, he attained his doctorate from the University of Chicago and began publishing academic

works the following year. The subjects of his early writings were not environmental; he published a study of administrative theory in 1944 and a study of New York state government in 1954. By 1964, however, Caldwell had shifted his emphasis, and he began to receive wide recognition for his work on environmental policy. In that year, he was presented with the William E. Mosher Award from the American Society for Public Administration for his article "Environment: A New Focus for Public Policy."

Caldwell's most important accomplishment was his prominent role in the drafting of the **National Environmental Policy Act** (NEPA) in 1969. As a consultant for the Senate Committee on Interior and Insular Affairs in 1968, he prepared *A Draft Resolution on a National Policy for the Environment*. His special report examined the constitutional basis for a national environmental policy and proposed a statement of intent and purpose for Congress. Many of the concepts first introduced in this draft resolution were later incorporated into the act. As consultant to that committee, Caldwell played a continuing role in the shaping of the NEPA, and he was involved in the development of the **environmental impact statement**.

In past years Caldwell has strongly defended the NEPA, as well as the regulatory agency it created, claiming that they represent "the first comprehensive commitment of any modern state toward the responsible custody of its environment." Although the act has influenced policy decisions at every level of government, the enforcement of its provisions have been limited. Caldwell argues that this is because environmental regulations have no clear grounding in the law. Statutes alone are often unable to withstand the pressure of economic interests. He has proposed an amendment to the Constitution as the best practical solution to this problem and he maintains that without such an amendment, environmental issues will continue to be marginalized in the political arena.

In addition to advising the Senate during the creation of the NEPA, Caldwell has done extensive work on international environmental policy. He has advised the Central Treaty Organization and served on special assignments in countries including Colombia, India, the Philippines, and Thailand. Currently, Caldwell serves as the Arthur F. Bentley Professor of Political Science emeritus and professor of public and environmental affairs at Indiana University in Bloomington, Indiana.

California condor

With a wingspan of over 9 ft (about 3 m), the California condor (*Gymnogyps californianus*) has the largest wingspan of any bird in North America. The condor is a **scavenger**. It is a member of the New World vulture family (Cathartidae), and is closely related to the Andean condor found in South America.

The California condor is an **endangered species** barely avoiding **extinction**. While the condor population may have been in decline before the arrival of Europeans in North America, increased settlement of its **habitat**, **hunting**, and indirect human influences (**pollution**, pesticides, construction hazards such as power lines) have almost wiped out the bird.

The condor was once found in much of North America. Fossil records indicate that it lived from Florida to New York in the East and British Columbia to Mexico in the West. The condor's range became more restricted even before European settlers arrived in North America. By the time Columbus arrived in North America (mid-fifteenth century), the condor had already started its retreat west. At the beginning of the twentieth century it could still be found in southern California and Baja California (northern Mexico), but by 1950 its range had been reduced to a strip of about 150 mi (241 km) at the southern end of the San Joaquin Valley in California.

In the 1940s, the **National Audubon Society** initiated a census of the condor population and recorded approximately 60 birds. In the early 1960s, the population was estimated at 42 birds. A 1966 survey found 51 condors, an increase that may have been due to variability among the sampling systems used. By the end of 1986 there were 24 condors alive, 21 of which were in captivity.

Direct and indirect human stressors are directly responsible for the decline in the condor population during the past three centuries. California condors have been shot by hunters and poisoned by bait set out to kill coyotes. Their food has been contaminated with pesticides such as DDT or **lead** from **lead shot** found in animal carcasses shot and lost by hunters. The condor's rarity has made their eggs a valuable commodity for unscrupulous collectors. Original food sources, such as mammoths and giant camels of the Pleistocene era, have disappeared, but as cattle ranching and sheep farming developed, carcasses of these animals have become suitable substitutes. Habitat destruction and general harassment reduced the condor's range and population to a

California condor (*Gymnogyps californianus*). (Photograph by Roy Toft. Tom Stack & Associates. Reproduced by permission.)

point where intervention was necessary to halt the bird's rapid decline to extinction.

Most other large birds and mammals in North America that lived during the late Pleistocene period have become extinct. However, there is a small chance that with intervention and restoration projects, the California condor can be saved from extinction. As a result, after much debate, the decision was made to remove all California condors from the wild and initiate a captive breeding and reintroduction program. The United States **Fish and Wildlife Service**, together with the California Fish and Game Commission, captured the last wild condor in April 1987.

The captive breeding program has thus far increased the condor population dramatically. Condors nest only once every two years and typically lay only one egg. By removing the egg from the nest for laboratory incubation, the female can be tricked into laying a replacement egg. This helps accelerate the population increase.

In January 1992, a pair of California condors was released into the wild. In October the male was found dead of kidney failure after apparently drinking from a pool of antifreeze in a parking lot near their sanctuary. Six additional condors were released at the end of 1992. In 1994, the total condor population consisted of nine wild condors and 66 birds in captivity. In 1995 another pair of captive birds was released into the wild, and with the release of more birds in following years, breeding pairs began to establish nest sites. In 2001, an egg that was laid by captive condors in the Los Angeles Zoo was placed in a condor nest in the wild, and the chick hatched successfully, only to die a few days later. The pair of condors then laid their own egg and hatched the first wild chick in April 2002. This was the first chick hatched in the wild in 18 years. As of April 2002, there were 63 free-living condors in California and Arizona and 18 more were awaiting release from field pens where they were being acclimated to their natural habitat. The captive population totaled 104 birds.

The California Condor Recovery Plan is a consortium of private groups and public agencies. The goal of the recovery plan is to have 150 condors in each of two separate populations with at least 15 breeding pairs in each group. However, there are significant obstacles to the recovery of wild populations of California condors. These include continued pressure from development that causes accidents such as collisions with power lines and **poisoning** by crude oil from drilling operations that the birds mistake for pools of water. Although the capture and release of this **species** is working and the population of captive birds is growing, the survival of the California condor in the wild is still in doubt. Measures must be taken to reduce risks to wild birds from man-made hazards.

John Baird Callicot (1941 –)

American environmental philosopher

J. Baird Callicott is a founder and seminal thinker in the modern field of environmental philosophy. He is best known as the leading contemporary exponent of Aldo Leopold's **land ethic**, not only interpreting Leopold's original works but also applying the reasoning of the land ethic to modern resource issues such as **wilderness** designation and **biodiversity** protection.

Callicott's 1987 edited volume, *Companion to A Sand County Almanac*, is the first interpretive and critical discussion of Leopold's classic work. His 1989 collection of essays, *In Defense of the Land Ethic*, explores the intellectual foundations and development of Leopold's ecological and philosophical insights and their ultimate union in his later works.

In 1991 Callicott, with Susan L. Flader, introduced to the public the best of Leopold's remaining unpublished and uncollected literary and philosophical legacy in a collection entitled *The River of the Mother of God and Other Essays* by **Aldo Leopold**.

Since his contribution to the inaugural issue of the journal *Environmental Ethics* in 1979, Callicott's articles and essays have appeared not only in professional philosophical journals and a variety of scientific and technical periodicals, but in a number of lay publications as well. He has contributed chapters to more than twenty books and is internationally known as an author and speaker. Born in Memphis, Tennessee, Callicott completed his Ph.D. in philosophy at Syracuse University in 1971, and has since held visiting professorships at a number of American universities. In 1971, while teaching at the University of Wisconsin-Stevens Point, Callicott designed and taught what is widely acknowledged as the nation's first course in **environmental ethics**. He is currently associate professor of Philosophy and Religion at the University of North Texas. With respect to the major value questions today in environmental ethics, Callicott's position can best be illustrated by his claim that there can be no value without valuers. He thus recognizes the legitimacy of both instrumental and intrinsic valuation on the part of a democracy of valuers, human and nonhuman.

Callicott perceives that we live today on the verge of a profound paradigm shift concerning human interactions with and attitudes toward the natural world. Much of his current work aims at distilling and giving voice to this shift and at articulating an ecologically accurate and philosophically valid concept of sustainability. This concept abandons dualistic (man versus **nature**), ethnocentric (modern Euroamerican), and static (e.g., wilderness frozen in time) elements of current thought in sustainability in favor of those emphasizing dynamic human/nonhuman **mutualism**, both in **ecosystem conservation** and in restoration. Through careful management consistent with the best ecological information and theories, Callicott believes, humans can not only protect but can and should enhance **ecosystem health**. His ideas challenge modern conventional wisdom and could radically alter much current theory in environmental philosophy as well as affect practice in wilderness management and economic development planning.

As one of a handful of scholars who launched the field of environmental ethics as we know it today, and as one of even fewer philosophers who have made their works accessible and pertinent not only to other academicians but to the general public, J. Baird Callicott occupies an important place in the history of modern philosophy. His work will undoubtedly continue to shape thinking on the ethical dimensions of resource management decisions for generations to come.

Canadian Forest Service

The Canadian **Forest Service** (CFS) is a federal government agency with a responsibility to conduct research and analyze information related to the sustainable use of the Canadian forest resource. Because of the importance of the forest industries to the Canadian economy, CFS is a department with its own minister in the federal cabinet.

In Canada, provincial and territorial governments have the responsibility for establishing allowable forest harvests and establishing criteria for acceptable management plans for provincial-crown land, which comprises the bulk of the economic forest resource of the nation. CFS integrates with relevant departments of the provinces and territories through the Canadian Council of Forest Ministers.

CFS operates six forest research centers in the regions of Canada, as well as two research institutes: the Petawawa National Forestry Institute at Chalk River, Ontario, and the Forest **Pest** Management Institute at Sault Ste. Marie, Ontario. Collectively, these institutions and their staff comprise the major force in forestry-related research in Canada.

The Government of Canada has committed to the practice of ecologically **sustainable forestry**, and CFS works with other levels of government, industry, educational institutions, and the public towards this end.

Research programs within CFS are diverse, and include activities related to tree anatomy, physiology, and productivity, techniques of **biomass** and stand inventory, determination of site quality, and research of forest harvesting practices, management practices aimed at increasing productivity and economic value, and forest pest management.

CFS also supports much of the **forest management** and research conducted within each of the provinces and territories, through joint federal-provincial Forest Development Agreements. CFS also supports much of the forestry research conducted at Canadian universities through research contracts and joint-awards programs with other government agencies and industry.

An important initiative, begun in 1992, is the Model Forest Program under Canada's *Green Plan*. The intent of this program is to provide substantial support for innovative forest management and research, conducted by integrated teams of partners involving industry, all levels of government, universities, non-government organizations, woodlot owners, and other groups and citizenry. A major criterion for success in the intense competition for funds towards a model forest is that the consortium of proponents demonstrate a vision of ecologically sustainable forest management, and a likely capability of achieving that result.

CFS's most recent endeavor is titles Forest 2020. This project was established at the 2001 Annual Meeting of Canadian Council of Forest Ministers (CCFM), and revolves around "incorporating wood fibre production through the establishment of plantations of fast growing high-yield tree **species**, and intensified silviculture in previously harvested, or second growth, forest areas."

Canadian Parks Service

The Canadian Parks Service (CPS) is the government agency charged with fulfilling the statutes and policies of Canada's national parks. The first **national park** was established in Banff, Alberta, in 1885, although parks were not institutionalized in Canada until 1911. The original policy and program established national parks to protect characteristic aspects of Canada's natural heritage, and, at the same time, cater to the benefit, enjoyment, and education of its people.

The National Parks Act of 1930 required parliamentary approval of parks, prohibited **hunting**, mining, and exploration, and limited forest harvesting. Other federal statutes gave control over lands and resources to the provinces, which meant land assembly for park development could not proceed without intergovernmental agreement. An amendment to the Parks Act increased the Park Service's ability to enforce regulations and levy meaningful penalties.

In 1971 the park system was expanded to include examples of all 39 terrestrial natural regions of Canada. Currently, 25 regions are represented by 39 parks. The Canadian government has pledged to develop sites in the remaining 14 regions in upcoming years. The CPS hopes that national parks will eventually encompass 12 percent of Canada's land base; they currently occupy only 1.8 percent.

Canada's four marine coasts have been classified into 29 regions, all of which are to be represented in a marine parks program. One site has been formally established, while four others are being considered. The CPS mandate was amended in 1986 to share control of marine parks with two other federal agencies, which manage fisheries and marine **transportation**.

Current park policy emphasizes the maintenance of **ecological integrity** over tourism and **recreation**. Much conflict, however, has centered on development within park boundaries. Townsites, highways, ski resorts, and **golf courses** provide public enjoyment, but conflict with the protective mandate of the parks' charter. Commercial and recreational fishing, **logging**, and **trapping** have also been allowed, despite legal prohibitions. In 1992, the Canadian Parks and **Wilderness Society** and the Sierra Legal Defense Fund successfully sued the Canadian government to stop logging in Wood Buffalo National Park, a protected **habitat** for both the endangered **whooping crane** and wood **bison**.

[*Amy A. Strumolo*]

Canadian Wildlife Service

The Canadian **Wildlife** Service (CWS) was established in 1947. Until 1971 it was governed by the federal government's Parks Branch in the Department of Indian and Northern Development. Since 1971 it has been a branch of **Environment Canada**, most recently under the **Conservation** and Protection division. The Service is served by five regional offices across Canada and is headquartered in Hull, Quebec. There are four branches within the CWS: the Migratory Birds and Conservation Branch; the North American Waterfowl Management Plan Implementation Branch; the Wildlife Toxicology and Surveys Branch/National Wildlife Research Centre; and the Program Analysis and Co-ordination Branch.

Wildlife matters were delegated to the provinces by the Canadian constitution, and responsibility is generally in the hands of provincial administrations. Federal-provincial cooperation was facilitated through meetings of the Federal-Provincial Wildlife Ministers Conferences, ongoing since 1922 and an annual event since 1945. Through those ongoing discussions, federal wildlife policy has developed mainly around areas of transboundary issues and problems deemed in the national interest. Currently, the CWS's primary responsibility is to enforce the Migratory Birds Convention Act, the Canada Wildlife Act, the Convention on Interna-

tional Trade in **Endangered Species** of Fauna and Flora (CITES), and the Ramsar **Convention on Wetlands of International Importance**. Furthermore, it has increased responsibility on federal lands, north of 60°N latitude, although in recent years much responsibility has been delegated to the territorial wildlife services and local co-management agreements with aboriginal peoples.

Within those statutes and agreements CWS is responsible for policy and strategy development, enforcement, research, public relations, education and interpretation, **habitat** classification, and the management of about 98 sanctuaries and 49 wildlife areas. The combination of a national and international mandates and diverse landscapes of Canada make CWS the pivotal **wildlife management** institution in Canada. However, CWS's increasing reliance on cooperative measures with provincial governments and nongovernmental organizations, including **Ducks Unlimited** Canada and **World Wildlife Fund** Canada, has led the organization to less direct management and more coordination activities. Critics of Canada's wildlife management direction have suggested that the once world-renowned repository of research expertise in CWS has suffered in recent years.

Cancer

A malignant tumor, cancer comprises a broad spectrum of malignant neoplasms classified as either carcinomas or sarcomas. Carcinomas originate in the epithelial tissues, while sarcomas originate from connective tissues and structures that have their origin in mesodermal tissue. Cancer is an invasive disease that spreads to various parts of the body. It spreads directly to those tissues immediately surrounding the primary site of the cancer and may spread to remote parts of the body through the lymphatic and circulatory systems.

Cancer occurs in most, if not all, multicellular animals. Evidence from fossil records reveal bone cancer in dinosaurs, and sarcomas have been found in the bones of Egyptian mummies. Hippocrates is credited with coining the term *carcinoma*, the Greek word for crab. Why the word for crab was chosen enjoys much speculation, but may have had to do with the sharp, biting pain and invasive, spreading nature of the disease.

A **carcinogen** is any substance or agent that produces or induces the development of cancer. Carcinogens are known to affect and initiate metabolic processes at the level of DNA (the information-storing molecules in cells). DNA damage (**mutation**) is the development of cancer after exposure to a carcinogen. This kind of mutation is actually reversible; our bodies continually experience DNA damage, which is continually being corrected. It is only when promoter cells intervene during cell proliferation that tumors begin to develop. Although several agents can induce cell division, only promoters induce tumor development.

An example of this process would be what happens in an epidermal cell, when its DNA undergoes rapid, irreversible alteration or mutation after exposure to a carcinogen. The cell undergoes proliferation, producing altered progeny, and it is at this point that the cell may proceed on one of two pathways. The cell may undergo interrupted exposure to promoters and experience early reversible precancerous lesions. Or it may experience continuous exposure to the promoters, thereby causing malignant cell changes. During the late phase of promotion, the primary epidermal cell becomes tumorous and begins to invade normal cells; then it begins to spread. It is at this stage that tumors are identified as malignant.

The spread of tumors throughout the body is believed to be governed by several processes. One possible mechanism is direct invasion of contiguous organs. This mechanism is poorly understood, but it involves multiplication, mechanical pressure, release of lytic enzymes, and increased motility of individual tumor cells. A second process is metastasis. This is the spread of cancer cells from a primary site of origin to a distant site, and it is the life-threatening aspect of malignancy. At present there are many procedures available to surgeons for successfully eradicating primary tumors; however, the real challenge in reducing cancer **mortality** is finding ways to control metastasis.

Clinical manifestations of cancer take on many forms. Usually little or no pain is associated with the early stages of malignant disease, but pain does affect 60–80% of those terminally ill with cancer. General mechanisms causing pain associated with cancer include pressure, obstruction, invasion of a sensitive structure, stretching of visceral surfaces, tissue destruction, and inflammation. Abdominal pain is often caused by severe stretching from the tumor invasion of the hollow viscus, as well as tumors that obstruct and distend the bowel. Tumor compression of nerve endings against a firm surface also creates pain. Brain tumors have very little space to grow without compressing blood vessels and nerve endings between the tumor and the skull. Tissue destruction from infection and necrosis can also cause pain. Frequently infection occurs in the oral area, in which a common cause of pain is ulcerative lesions of the mouth and esophagus.

Cancer treatments involve chemotherapy, radiotherapy, surgery, immunotherapy, and combinations of these

Frequency of Cancer-Related Death

Cancer Site	Number of Deaths Per Year
Lung	160,100
Colon and rectum	56,500
Breast	43,900
Prostate	39,200
Pancreas	28,900
Lymphoma	26,300
Leukemia	21,600
Brain	17,400
Stomach	13,700
Liver	13,000
Esophagus	11,900
Bladder	12,500
Kidney	11,600
Multiple myeloma	11,300

modalities. Chemotherapy and its efficacy is related to how the drug enters the cell cycle; the design of the therapy is to destroy enough malignant cells so that the body's own immune system can destroy the remaining cells naturally. Smaller tumors with rapid growth rates seem to be most responsive to chemotherapy. Radiation therapy is commonly used to eradicate tumors without excessive damage to surrounding tissues. Radiation therapy attacks the malignant cell at the DNA level, disrupting its ability to reproduce. Surgery is the treatment of choice when it has been determined that the tumor is intact and has not metastasized beyond the limits of surgical excision. Surgery is also indicated for benign tumors that could progress into malignant tumors. Premalignant and in situ tumors of epithelial tissues, such as skin, mouth, and cervix, can be removed.

Chemotherapy and radiation treatments are the most commonly used therapies for cancer. Unfortunately, both methods produce unpleasant side effects; they often suppress the immune system, making it difficult for the body to destroy the remaining cancer even after the treatment has been successful. In this regard, immunotherapy holds great promise as an alternative treatment, because it makes use of the unique properties of the immune system.

Immunotherapies for the treatment of cancer are generally referred to as biological response modifiers (BRMs). BRMs are defined as mammalian gene products, agents, and clinical protocols that affect biologic responses in host-tumor interactions. Immunotherapies have a direct cytotoxic effect on cancer cells, initiation or augmentation of the host's tumor-immune rejection response, and modification of cancer cell susceptibility to the lytic or tumor static effects of the immune system. As with other cancer therapies immunotherapies are not without their own side effects. Most common are flu-like symptoms, skin rashes, and vascular-leak syndrome. At their worst, these symptoms are usually less severe than those of current chemotherapy and radiation treatments. *See also* Hazardous material; Hazardous waste; Leukemia; Radiation sickness

Captive propagation and reintroduction

Captive propagation is the deliberate breeding of wild animals in captivity in order to increase their numbers. Reintroduction is the deliberate release of these **species** into their native **habitat**. The Mongolian wild horse, Pere David's deer, and the American **bison** would probably have become extinct without captive propagation. Nearly all cases of captive propagation and reintroduction involve threatened or **endangered species**. Zoos are increasingly involved in captive propagation, sometimes using new technologies. One of these, allows a relatively common species of antelope to act as a surrogate mother and give birth to a **rare species**.

Once suitable sites are selected, a reintroduction can take one of three forms. *Reestablishment reintroductions* take place in areas where the species once occurred but is now entirely absent. Recent examples include the red wolf, the **black-footed ferret**, and the **peregrine falcon** east of the Mississippi River. Biologists use *augmentation reintroduction* to release captive-born wild animals into areas in which the species still occurs but only in low numbers. These new animals can help increase the size of the population and enhance genetic diversity. Examples include a small Brazilian monkey called the golden lion tamarin and the peregrine falcon in the western United States. A third type, *experimental reintroduction*, acts as a test case to acquire essential information for use on larger-scale permanent reintroductions. The red wolf was first released as an experimental reintroduction. A 1982 amendment to the **Endangered Species Act** facilitates experimental reintroductions, offering specific exemptions from the Act's protection, allowing managers greater flexibility should reintroduced animals cause unexpected problems.

The release of baby Kemp's ridley sea turtles on a beach in Mexico. (Photograph by C. Allan Morgan. Peter Arnold Inc. Reproduced by permission.)

Yet captive propagation and reintroduction programs have their drawbacks, the chief one being their high cost. Capture from the wild, food, veterinary care, facility use and maintenance all contribute significant costs to maintaining an animal in captivity. Other costs are incurred locating suitable reintroduction sites, preparing animals for release, and monitoring the results. Some conservationists have argued that the money would be better spent acquiring and protecting habitat in which remnant populations already live.

There are also other risks associated with captive propogation programs such as disease, but perhaps the greatest biological concern is that captive populations of endangered species might lose learned or genetic traits essential to their survival in the wild. Animals fed from birth, for example, might never pick up food-gathering or prey-hunting skills from their parents as they would in the wild. Consequently, when reintroduced such animals may lack the skill to feed themselves effectively. Furthermore, captive breeding of animals over a number of generations could affect their **evolution**. Animals that thrive in captivity might have a selective advantage over their "wilder" cohorts in a **zoo**, but might be disadvantaged upon reintroduction by the very traits that aided them while in captivity.

Despite these shortcomings, the use of captive propagation and reintroduction will continue to increase in the decades to come. Biologists learned a painful lesson about the fragility of endangered species in 1986 when a sudden outbreak of canine distemper decimated the only known group of black-footed ferrets. The last few ferrets were taken into captivity where they successfully bred. Even as new ferret populations become established through reintroduction, some ferrets will remain as captive breeders for insurance against future catastrophes. Biologists are also steadily improving their methods for successful reintroduction. They have learned how to select the combinations of sexes and ages that offer the best chance of success and have developed systematic ways to choose the best reintroduction sites.

Captive propagation and reintroduction will never become the principal means of restoring threatened and endangered species, but it has been proven effective and will continue to act as insurance against sudden or catastrophic losses

in the wild. *See also* Biodiversity; Extinction; Wildlife management; Wildlife rehabilitation

Carbon

The seventeenth most abundant element on earth, carbon occurs in at least six different allotropic forms, the best known of which are diamond and graphite. It is a major component of all biochemical compounds that occur in living organisms: carbohydrates, proteins, lipids, and nucleic acids. Carbon-rich rocks and minerals such as limestone, gypsum, and marble often are created by accumulated bodies of aquatic organisms. Plants, animals, and **microorganisms** cycle carbon through the **environment**, converting it from simple compounds like **carbon dioxide** and **methane** to more complex compounds like sugars and starches, and then, by the action of **decomposers**, back again to simpler compounds. One of the most important **fossil fuels**, **coal**, is composed chiefly of carbon.

Carbon cycle

Carbon makes up no more than 0.27% of the mass of all elements in the universe and only 0.0018% by weight of the elements in the earth's crust. Yet, its importance to living organisms is far out of proportion to these figures. In contrast to its relative **scarcity** in the **environment**, it makes up 19.4% by weight of the human body. Along with **hydrogen**, carbon is the only element to appear in every organic molecule in every living organism on earth.

The series of chemical, physical, geological, and biological changes by which carbon moves through the earth's air, land, water, and living organisms is called the carbon cycle.

In the **atmosphere**, carbon exists almost entirely as gaseous **carbon dioxide**. The best estimates are that the earth's atmosphere contains 740 billion tons of this gas. Its global concentration is about 350 **parts per million** (ppm), or 0.035% by volume. That makes carbon dioxide the fourth most abundant gas in the atmosphere after **nitrogen**, oxygen and argon. Some carbon is also released as **carbon monoxide** to the atmosphere by natural and human mechanisms. This gas reacts readily with oxygen in the atmosphere, however, converting it to carbon dioxide.

Carbon returns to the hydrosphere when carbon dioxide dissolves in the oceans, as well as in lakes and other bodies of water. The solubility of carbon dioxide in water is not especially high, 88 milliliters of gas in 100 milliliters of water. Still, the earth's oceans are such a vast **reservoir** that experts estimate that approximately 36,000 billion tons of carbon are stored there. They also estimate that about 93 billion tons of carbon flows from the atmosphere into the hydrosphere each year.

Carbon moves out of the oceans in two ways. Some escapes as carbon dioxide from water solutions and returns to the atmosphere. That amount is estimated to be very nearly equal (90 billion tons) to the amount entering the oceans each year. A smaller quantity of carbon dioxide (about 40 billion tons) is incorporated into aquatic plants.

On land, green plants remove carbon dioxide from the air through the process of photosynthesis—a complex series of chemical reactions in which carbon dioxide is eventually converted to starch, cellulose, and other carbohydrates. About 100 billion tons of carbon are transferred to green plants each year, and a total of 560 billion tons of the element is thought to be stored in land plants alone.

The carbon in green plants is eventually converted into a large variety of organic (carbon-containing) compounds. When green plants are eaten by animals, carbohydrates and other organic compounds are used as raw materials for the manufacture of thousands of new organic substances. The total collection of complex organic compounds stored in all kinds of living organisms represents the reservoir of carbon in the earth's **biosphere**.

The cycling of carbon through the biosphere involves three major kinds of organisms. Producers are organisms with the ability to manufacture organic compounds such as sugars and starches from inorganic raw materials such as carbon dioxide and water. Green plants are the primary example of producing organisms. Consumers are organisms that obtain their carbon (that is, their food) from producers: all animals are consumers. Finally, **decomposers** are organisms such as bacteria and **fungi** that feed on the remains of dead plants and animals. They convert carbon compounds in these organisms to carbon dioxide and other products. The carbon dioxide is then returned to the atmosphere to continue its path through the carbon cycle.

Land plants return carbon dioxide to the atmosphere during the process of **respiration**. In addition, animals that

eat green plants exhale carbon dioxide, contributing to the 50 billion tons of carbon released to the atmosphere by all forms of living organisms each year. Respiration and **decomposition** both represent, in the most general sense, a reverse of the process of **photosynthesis**. Complex organic compounds are oxidized with the release of carbon dioxide and water—the raw materials from which they were originally produced.

At some point, land and aquatic plants and animals die and decompose. When they do so, some carbon (about 50 billion tons) returns to the atmosphere as carbon dioxide. The rest remains buried in the earth (up to 1,500 billion tons) or on the ocean bottoms (about 3,000 billion tons). Several hundred million years ago, conditions of burial were such that organisms decayed to form products consisting almost entirely of carbon and **hydrocarbons**. Those materials exist today as pockets of the fossil fuels—coal, oil, and **natural gas**. Estimates of the carbon stored in **fossil fuels** range from 5,000 to 10,000 billion tons.

The processes that make up the carbon cycle have been occurring for millions of years, and for most of this time, the systems involved have been in equilibrium. The total amount of carbon dioxide entering the atmosphere from all sources has been approximately equal to the total amount dissolved in the oceans and removed by photosynthesis. However, a hundred years ago changes in human society began to unbalance the carbon cycle. The Industrial Revolution initiated an era in which the burning of fossil fuels became widespread. In a short amount of time, large amounts of carbon previously stored in the earth as **coal**, oil, and natural gas were burned up, releasing vast quantities of carbon dioxide into the atmosphere.

Between 1900 and 1992, measured concentrations of carbon dioxide in the atmosphere increased from about 296 ppm to over 350 ppm. Scientists estimate that fossil fuel **combustion** now released about five billion tons of carbon dioxide into the atmosphere each year. In an equilibrium situation, that additional five billion tons would be absorbed by the oceans or used by green plants in photosynthesis. Yet this appears not to be happening: measurements indicate that about 60% of the carbon dioxide generated by fossil fuel combustion remains in the atmosphere.

The problem is made even more complex because of **deforestation**. As large tracts of forest are cut down and burned, two effects result: carbon dioxide from forest fires is added to that from other sources, and the loss of trees decreases the worldwide rate of photosynthesis. Overall, it appears that these two factors have resulted in an additional one to two billion tons of carbon dioxide in the atmosphere each year.

No one can be certain about the environmental effects of this disruption of equilibria in the carbon cycle. Some authorities believe that the additional carbon dioxide will augment the earth's natural **greenhouse effect**, resulting in long-term global warming and **climate** change. Other argue that we still do not know enough about the way oceans, clouds, and other factors affect climate to allow such predictions.

This controversy involves a difficult choice. Should actions that could potentially cost billions of dollars be taken to reduce the **emission** of carbon dioxide when evidence for climate change is still uncertain? Or should governments wait until that evidence becomes more clear, with the risk that needed actions may then come too late.

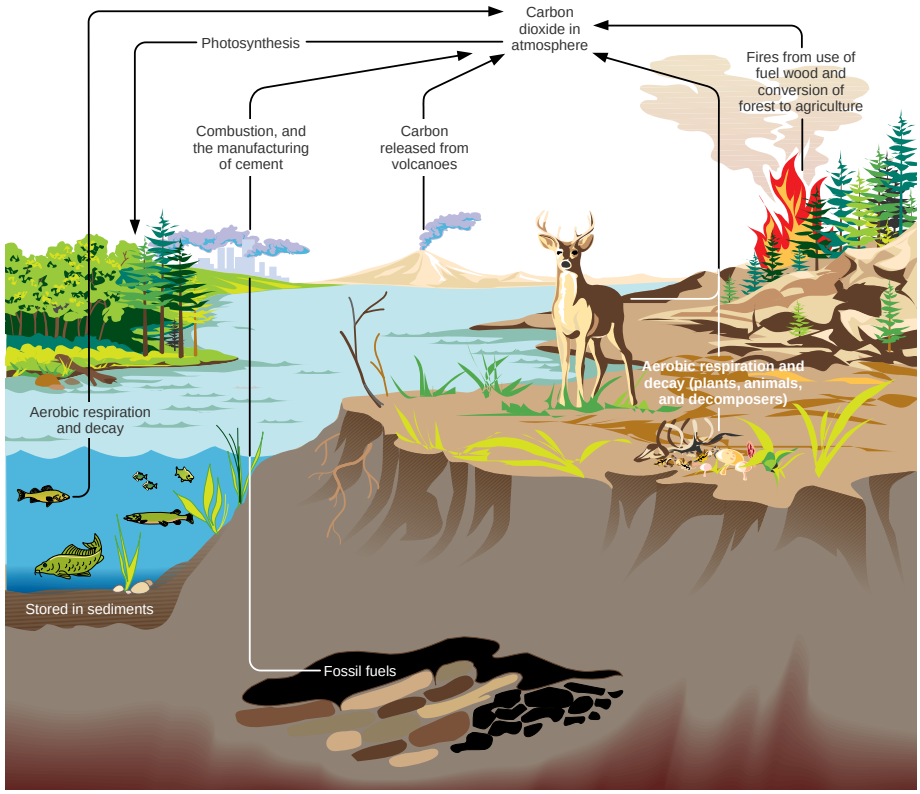
Carbon dating



see **Radiocarbon dating**

Carbon dioxide

The fourth most abundant gas in the earth's **atmosphere**, **carbon** dioxide occurs in an abundance of about 350 **parts per million**. The gas is released by volcanoes and during **respiration**, **combustion**, and decay. Plants convert carbon dioxide into carbohydrates by the process of **photosynthesis**. Carbon dioxide normally poses no health hazard to humans. An important factor in maintaining the earth's **climate**, molecules of carbon dioxide capture heat radiated from the earth's surface, raising the planet's temperature to a level at which life can be sustained, a phenomenon known as the **greenhouse effect**. Some scientists believe that increasing levels of carbon dioxide resulting from human activities are now contributing to a potentially dangerous global warming.

Carbon emissions trading

Carbon emissions trading (CET) is a practice allowing countries—and corporations—to trade their harmful carbon emissions for credit to meet their designated carbon **emission** limits. Most developed countries approved this system in 1992 when the United Nations Framework Convention on Climate Change (UNFCCC) was presented. The document provided for limits on greenhouse gas emissions in an attempt to stem the determination of climate change around the world. The

Carbon cycle. (Illustration by Hans & Cassidy.)

United States as of 2001 had backed away from the Kyoto Treaty stating similar restriction but would remain obligated in some regard to the UNFCCC. At least in theory, CET allows one country who might not be maintaining their target to trade credits with others that are well under theirs.

According to information from the Australian Academy of Science, in *Nova: Science in the news,* **carbon dioxide** (CO2) is known as a "greenhouse gas" ones that came out of the Earth's crust before life was known to begin, helping to stabilize the earth's temperatures in order to sustain life. The "greenhouse effect" occurs when the sun's heat energy passes through the **atmosphere** and warms up the earth with no interference. The Earth then radiates that same energy back into space. Other **greenhouse gases** include, water vapor (the primary greenhouse gas), **methane**, **ozone**, **carbon monoxide**, and **nitrous oxide**. All of these absorb part of this energy and send it in all directions—including the Earth. By the twenty-first century however, the emissions of greenhouse gases were not in the balance they had been for ages due to human activity, particularly that of burning **fossil fuels** such as **coal**, oil, and **natural gas**. Due to that, and to industrial development as well as residential development in the developed countries, forests were cleared at such a rate that inclined some scientists to wonder whether these practices were harmful in the significantly increased emissions of greenhouse gases.

The **Environmental Protection Agency** (EPA) launched a method of emissions trading known as, Online Allowance Transfer System (OATS). It is an online system that allows companies engaged in the **sulfur dioxide** and **nitrogen** oxide to record trades directly through the internet without having to file papers with the EPA. No such method yet exists for CET. In view of possible future issues regarding the trades in the United States in February 2002, Senators John McCain (R.-Ariz) and Sam Brownback(R.-Kan.) jointly introduced legislation that propsed establishing a national voluntary registry for companies to register carbon emission reductions. According to *Coal Age* "The propsal is a step toward developing a 'cap-and-trade' carbon emissions control program." Senators McCain and Leiberman (D.-CT) are also working on legislation that supports carbon emissions trading. McCain, noted *Coal Age* said that, "The registry would support current voluntary trading practices in private industry and other nongovernmental organizations."

The real issue that has resulted from CET is the trading market that has emerged. Opinions are varied regarding the advisability, and inherent dangers of CET. The International Carbon Bank & Exchange offered insight on CET through its web site. "Emissions trading reduces costs by allowing a field of players to achieve emissions redutions using market mechanisms. Over time, these mechanisms will drive emissions down and finance the shift to clean energy."

In August 2001, the Joyce Foundation granted $760,100 to fund the design phase of the Chicago Climate Exchange (CCX). The grant was actually directed to the J. L. Kellogg Graduate School of Management at Northwestern University in support of the work being done by Dr. Richard Sandor, an internationally-known trader. With the presidential administration of George W. Bush hesitant to apply a "cap-and-trade" system, the direction of the CCX and open market trading is viewed as providing a desirable alternative—particularly in light of the United States withdrawal from the Kyoto Treaty. According the *Environmental News Network (ENN)* in an article on the new design program, "The CCX's stated goal is to reduce participants' greenhouse gas emissions by five percent below 1999 levels over five years. By comparison, the countries that ratified the Kyoto Protocol must reduce emissions of carbon dioxide to an average of 5.2% below 1990 levels during the five-year period 2008 to 2012." By November 2001, the cities of Chicago and Mexico City announced their participation in CET by joining the CCX, with Chicago becoming the first American city to do so. Chicago's Mayor Richard Daley became honorary chair of the exchange, still in the design phase. He noted that, "For years our financial exchanges have been a vital parto f the local and naitonal economy. This is a good example of the kind of innovation that will help us solve our energy and environmental problems," according to the *Environment News Service.* Other businesses and agencies participating in the design phase of the CCX including, Agrilance, a partnership of agricultural producer-owners, local cooperatives and regional cooperatives; BP; Cinergy; **Ducks Unlimited**; DuPont; the energy company, Exeton; International Paper; the Iowa Farm Bureau Federation; Manitoba (CA) Hydro; National Council of Farmer Cooperatives; PG&E National Energy Group; Suncor Energy; Swiss Re, a reinsurance firm; **The Nature Conservancy**; and, Waste Energy.

On a broader scope of international trading, however, the United States' withdrawal from Kyoto was posing a possible problem. Due to the lack of participation, U.S. companies were seeing a possible short-term advantage in international business competition due to lower costs without the emissions trading—but those same companies, such as DuPont, already cutting emissions, might face the long-term shortchange depending on which way the international climate change policy could effect trading those emissions. In March 2002, Julie Vorman writing on the CET market for *Reuters* quoted Eileen Claussen, president of the Pew Center on Global Climate Change, noting that, "Despite the United States inaction, it is abundantly clear that we are beginning to see the outlines of a genuine greenhouse gas market." Also, according to Vorman, "The Pew Center report said more than 65 trades of greenhouse gas emissions totaling 55 million to 77 million tons have occurred over the past five years [since the 1997 Kyoto Protocol was introduced] but that those gifures probably underestimate the market activity. The emissions reductions traded for between 60 cents and $3.50 (U.S. dollars) per ton of carbon dioxide equivalent. (The date did not include trades within BP Pic and Royal Dutch Shell, which launched their own internal cap-and-trade programs in 1998 to cut emissions.)

The role of the agricultural industry in CET was being explored along with its options with the CCX. According to the American Farm Bureau, one of the plans under consideration was a plan to pay farmers for agricultural practices reducing carbon emissions into the atmosphere. "Farmers would be compensated for implementing or continuing practices that reduce carbon emissions from the soils. Such practices include reducing tillage, conserving tillage, retiring cropland, fertilizing with livestock manure, decreasing methane and reducing energy use. The compensation could potentially come from the government or companies that are interested in "trading" carbon credits." The Kyoto Protocol does not provide that option; but the Untied States wanted to consider it as a part of the UNFCCC. Jon Doggett, a senior director of governmental relations for the American Farm Bureau Federation (AFBF) added the caveat that such a practice of carbon sequestration in the soil—a practice some Americans support in opposition to European leaders who do not have the amount of land for such a program to succeed as does the United States—could be harmful to farmers in the long-term. Doggett noted that, "The industries that will be required to purchase the carbon credits supply farmers with vital operating materials, including fuel and **fertilizer**. As regulatory costs for companies rise, farmers will pay for that as fuel and fertilizer costs go up. The AFBF also pointed out that such storage might disrupt other environmetally beneficial practices—such as that employed by California producers after harvest when they flood their land and provide a **habitat** for geese and ducks. The issues of trading the benefits of one environmental concern for that of another would remain a matter of debate well into the century, no doubt.

Environmentalists continued to express concern that CET practices, particularly ones that were regulated voluntarily on the open market, would not reduce the greenhouse

gases to the extent that some scientists thought crucial to the planet's optimum survival. The ongoing debate on the theory of global warming raged on in the United States particularly. Business and industrial interests questioned the soundness of the theory, and worried that it would create serious obstacles to profits that might be translated into the research necessary for better energy alternatives. Those supporting the theory were concerned with declining standards for **pollution** controls that might enhance the **greenhouse effect**. The voluntary controls industry and countries would place on themselves were nonetheless considered the first step to creating a cleaner **environment**.

Carbon monoxide

A colorless, odorless, tasteless gas that is produced in only very small amounts by natural processes. By far the most important source of the gas is the incomplete **combustion** of **coal**, oil, and **natural gas**. In terms of volume, **carbon** monoxide is the most important single component of **air pollution**. Environmental scientists rank it behind sulfur oxides, **particulate** matter, **nitrogen oxides**, and volatile organic compounds, however, in terms of its relative hazard to human health. In low doses, carbon monoxide causes headaches, nausea, fatigue, and impairment of judgment. In larger amounts, it causes unconsciousness and death.

Carbon offsets (CO_2-emission offsets)

Many human activities result in large emissions of **carbon dioxide** (CO_2) and other so-called **greenhouse gases** into the **atmosphere**. Especially important in this regard are the use of **fossil fuels** such as **coal**, oil, and **natural gas** to generate electricity, to heat spaces, and as a fuel for vehicles. In addition, the disturbance of forests results in large emissions of CO_2 into the atmosphere. This can be caused by the conversion of forests into agricultural or urbanized land uses, and also by the harvesting of timber.

During the past several centuries, human activities have resulted in large emissions of CO_2 into the atmosphere, causing substantial increases in the concentrations of that gas. Prior to 1850 the atmospheric concentration of CO_2 was about 280 ppm, while in 1997 it was about 360 ppm. Other greenhouse gases (these are also known as radiatively active gases) have also increased in concentration during that same period: **methane** (CH_4) from about 0.7 ppm to 1.7 ppm, **nitrous oxide** (N_2O) from 0.285 ppm to 0.304 ppm, and **chlorofluorocarbons** (CFCs) from zero to 0.7 ppb.

Many climatologists and environmental scientists believe that the increased concentrations of radiatively active gases are causing an increase in the intensity of Earth's **greenhouse effect**. The resulting climatic warming could result in important stresses for both natural ecosystems and those that humans depend on for food and other purposes (agriculture, forestry, and fisheries). Overall, CO_2 is estimated to account for about 60% of the potential enhancement of the greenhouse effect, while CH_4 accounts for 15%, CFCs for 12%, **ozone** (O_3) for 8%, and N_2O for 5%.

Because an intensification of Earth's greenhouse effect is considered to represent a potentially important environmental problem, planning and other actions are being undertaken to reduce the emissions of radiatively active gases. The most important strategy for reducing CO_2 emissions is to lessen the use of fossil fuels. This will mostly be accomplished by reducing energy needs through a variety of **conservation** measures, and by switching to non-fossil fuel sources. Another important means of decreasing CO_2 emissions is to prevent or slow the rates of **deforestation**, particularly in

tropical countries. This strategy would help to maintain organic **carbon** within ecosystems, by avoiding the emissions of CO_2 through burning and **decomposition** that occur when forests are disturbed or converted into other land uses.

Unfortunately, fossil-fuel use and deforestation are economically important activities in the modern world. This circumstance makes it extremely difficult for society to rapidly achieve large reductions in the emissions of CO_2. An additional tactic that can contribute to net reductions of CO_2 emissions involves so-called CO_2 offsets. This involves the management of ecosystems to increase both the rate at which they are fixing CO_2 into plant **biomass** and the total quantity stored as organic carbon. This biological fixation can offset some of the emissions of CO_2 and other greenhouse gases through other activities.

Offsetting CO_2 emissions by planting trees

As plants grow, their rate of uptake of atmospheric CO_2 through **photosynthesis** exceeds their release of that gas by **respiration**. The net effect of these two physiological processes is a reduction of CO_2 in the atmosphere. The biological fixation of atmospheric CO_2 by growing plants can be considered to offset emissions of CO_2 occurring elsewhere—for example, as a result of deforestation or the **combustion** of fossil fuels.

The best way to offset CO_2 emissions in this way is to manage ecosystems to increase the biomass of trees in places where their density and productivity are suboptimal. The carbon-storage benefits would be especially great if a forest is established onto poorer-quality farmlands that are no longer profitable to manage for agriculture (this process is known as afforestation, or conversion into a forest). However, substantial increases in carbon storage can also be obtained whenever the abundance and productivity of trees is increased in "low-carbon ecosystems," including urban and residential areas.

Over the longer term, it is much better to increase the amounts of organic carbon that are stored in terrestrial ecosystems, especially in forests, than to just enhance the rate of CO_2 fixation by plants. The distinction between the amount stored and the rate of fixation is important. Fertile ecosystems, such as marshes and most agroecosystems, achieve high rates of net productivity, but they usually store little biomass and therefore over the longer term cannot sequester much atmospheric CO_2. A less extreme example involves second-growth forests and plantations, which have higher rates of net productivity than do older-growth forests. Averaged over the entire cycle of harvest and regeneration, however, these more-productive forests store smaller quantities of organic carbon than do older-growth forests, particularly in trees and large-dimension woody debris.

Both the greenhouse effect and emissions of CO_2 (and other radiatively active gases) are global in their scale and effects. For this reason, projects to gain CO_2 offsets can potentially be undertaken anywhere on the planet, but tallied as carbon credits for specific utilities or industrial sectors elsewhere. For example, a fossil-fueled electrical utility in the United States might choose to develop an afforestation offset in a less-developed, tropical country. This might allow the utility to realize significant economic advantages, mostly because the costs of labor and land would be less and the trees would grow quickly due to a relatively benign **climate** and long growing season. This strategy is known as a joint-implementation project, and such projects are already underway. These involve United States or European electrical utilities supporting afforestation in tropical countries as a means of gaining carbon credits, along with other environmental benefits associated with planting trees. Although this is a valid approach to obtaining carbon offsets, it can be controversial because some people would prefer to see industries develop forest-carbon offsets within the same country where the CO_2 is being emitted.

Afforestation in rural areas

An estimated 5–8 billion acres (2–3 billion ha) of deforested and degraded agricultural lands may be available world-wide to be afforested. This change in **land use** would allow enormous quantities of organic carbon to be stored, while also achieving other environmental and economic benefits. In North America, millions of acres of former agricultural land have reverted to forest since about the 1930s, particularly in the eastern states and provinces. There are still extensive areas of economically marginal agricultural lands that could be afforested in parts of North America where the climate and soils are suitable for supporting forests.

Agricultural lands typically maintain about one-tenth or less of the plant biomass of forests, while agricultural soils typically contain 60–80% as much organic carbon as forest soils. Because agricultural sites contain a relatively small amount of organic carbon, reforestation of those lands has a great potential for providing CO_2 offsets.

It is also possible to increase the amounts of carbon stored in existing forests. This can be done by allowing forests to develop into an old-growth condition, in which carbon storage is relatively great because the trees are typically big, and there are large amounts of dead biomass present in the surface litter, dead standing trees, and dead logs lying on the forest floor. Once the old-growth condition is reached, however, the **ecosystem** has little capability for accumulating "additional" carbon. Nevertheless, old-growth forests provide an important ecological service by tying up so much carbon in their living and dead biomass. In this sense, maintaining old-growth forests represents a strategy of CO_2-emissions deferral, because if those "high-carbon"

ecosystems were disturbed by timber harvesting or conversion into another kind of land use, a result would be an enormous **emission** of CO_2 into the atmosphere.

Dixon *et al.* (1993) examined carbon-offset projects in various parts of the world, most of which involved afforestation of rural lands. The typical costs of the afforestation projects were $1–10 per ton of carbon fixed. These are only the costs associated with planting and initial tending of the growing trees; there might also be additional expenses for land acquisition and stand management and protection.

Of course, even while rural afforestation provides large CO_2-emission offsets, other important benefits are also provided. In some cases, the forests might be used to provide economic benefits through the harvesting of timber (although the resulting disturbance would lessen the carbon-storage capability). Even if trees are not harvested from the CO_2-offset forests, it would be possible to hunt animals such as deer, and to engage in other sorts of economically valuable outdoor **recreation**. Increasing the area of forests also provides many non-economic benefits, such as providing additional **habitat** for native **species**, and enhancing ecological services related to clean water and air, **erosion** control, and climate moderation.

Urban forests

Urban forests consist of trees growing in the vicinity of homes and other buildings, in areas where the dominant character of land use is urban or suburban. Urban forests may originate as trees that are spared when a forested area is developed for residential land use, or they may develop from saplings that are planted after homes are constructed. Urban forests in older residential neighborhoods generally have a relatively high density and extensive canopy cover of trees. These characters are less well developed in younger neighbourhoods and where land use involves larger buildings used by institutions, business, or industry.

There are about 70 million acres (28-million ha) of urban land in the United States. Its urban forest supports an average density of 20 trees/acre (52 trees/ha), and has a canopy cover of 28%. Nowak *et al.* (1994) estimated that urban areas of the United States contain about 225 million tree-planting opportunities, in which suboptimal tree densities could be subjected to fill-planting.

Urban forests achieve carbon offsets in two major ways. First, as urban trees grow they sequester atmospheric CO_2 into their increasing biomass. The average carbon storage in urban trees in the United States is about 13 tons per acre (33 tonnes per ha). On a national basis that amounts to 0.8 billion tonnes of organic carbon, and an annual rate of uptake of six million tonnes.

In addition, urban trees can offset some of seasonal use of energy for cooling and heating the interior spaces of buildings. Large, well-positioned trees provide a substantial cooling influence through shading. Trees also cool the **ambient air** by evaporating water from their foliage (a process known as **transpiration**). Trees also decrease wind speeds near buildings. This results in decreased heating needs during winter, because less indoor warmth is lost by the **infiltration** of outdoor air into buildings. Over most of North America larger energy offsets associated with urban trees are due to decreased costs of cooling than with decreased heating costs. In both cases, however, much of the energy conserved represents decreased CO_2 emissions through the combustion of fossil fuels.

It is considerably more expensive to obtain CO_2-offset credits using urban trees than with rural trees. This difference is mostly due to urban trees being much larger than rural trees when planted, while also having larger maintenance expenses. In the survey of Dixon *et al.* (1993), the typical costs of rural CO_2-offset projects were $1–10 per ton of carbon fixed, compared with $15–30 per ton for urban trees.

Another study estimated the carbon savings associated with planting 100-million trees in urban areas in the United States (Nowak *et al.*, 1994). In this case, the total CO_2-emission offsets were estimated to be 58.2 kg C per tree per year (for trees at least ten years old). About 90% of the total CO_2 offsets was associated with indirect savings of energy for cooling and heating buildings, and 10% with carbon sequestration into the growing biomass of the trees. The estimated costs of the carbon offsets were $6.6–27.5 per ton of carbon, but these costs would decrease considerably as the trees grew larger. This study estimated that planting trees in urban areas of the United States could potentially offset as much as 2% of this country's emissions of CO_2.

Carbon tax

To limit and control the amount of **carbon dioxide** (CO_2) added to the **atmosphere**, special taxes, called **carbon** taxes, have been proposed and in some cases adopted, on fuels containing carbon. Fuels such as **coal**, **gasoline**, heating oil, and **natural gas**, release energy by combining the carbon they contain with oxygen in the air, to produce carbon dioxide. Increased use of carbon-containing **fossil fuels** in modern times has greatly increased the rate at which carbon dioxide is entering the atmosphere. Measurable increases in atmospheric levels of the gas have been detected. Since carbon dioxide is the principle component of so-called **greenhouse gases**, changes in its concentration in the earth's atmosphere are a concern. Increases in the level of carbon dioxide, and other greenhouse gases such as **methane**, **nitrous oxide**, **ozone**, and man-made **chlorofluorocarbons** can be expected to result in warmer temperatures on the surface of the earth, and wide-ranging changes in the global **climate**. Greenhouse gases permit radiation from the Sun to reach the earth's surface but prevent the infrared or heat component of sunlight from re-irradiating into space.

The wide spread concern over the possible climatic effects of increases in heat-trapping gases in the atmosphere was exemplified by a 1994 report of the **Intergovernmental Panel on Climate Change** (IPCC) which concluded that unless greenhouse gas emissions were curtailed, average global temperatures would rise 2.5–8.1° F (1.4–4.5° C) by the year 2100. A 20% reduction in emissions over 20 years was recommended and considered feasible in developed countries. It was recognized that the rapidly expanding economies of many developing countries makes similar reductions less likely.

While limiting the buildup of heat-trapping gases in the atmosphere has been a goal of natural scientists for some time, many economists have now joined the effort. In 1997, 2,000 prominent economists, including six Nobel Laureates, signed the "Economists' Statement on Climate Change" stating that policies to slow global warming are needed and are economically viable. The economists agreed with a review conducted by a distinguished international panel of scientists under the auspices of the IPCC that, "The balance of evidence suggests a discernible human influence on global climate." They further stated that, "As economists, we believe that global climate change carries with it significant environmental, economic, social, and geopolitical risks, and that preventive steps are justified." They state that economic studies have found that potential policies to reduce greenhouse-gas emissions can be designed so that benefits outweigh costs, and living standards would not be harmed. They claim that United States productivity may actually improve as a result. The statement goes on to claim that, "the most efficient approach to slowing climate change is through market-based policies" rather than limits or regulations. The economists also suggest that, "A cooperative approach among nations is required, such as an international emissions trading agreement." They recommend, "market mechanisms such as carbon taxes or the auction of emissions permits." Their statement goes on to suggest that, "Revenues generated from such policies can effectively be used to reduce budget deficits or lower existing taxes." New taxes are never popular, but are more apt to be accepted when the revenue is used to replace other taxes or to aid the **environment**.

As in any public policy debate, views of even well-qualified experts are often sharply divided. Some industry representatives and scientists are unwilling to accept the premise that greenhouse gas emissions represent a serious threat. Industrial spokesmen continue to claim that efforts to reduce greenhouse gas emissions through taxation or other economic means are not cost effective, and would devastate the economy, cost jobs, and reduce living standards. Individual countries worry about the impacts on their competitiveness if other countries do not adopt similar measures. The potential impact on low-income groups must also be considered. Some are concerned that the taxes have to be high to be effective. The amount of year to year variation in climate and temperature throughout the globe, provide ample room for differences of opinion.

International attention was focused on the need to reduce greenhouse gases at the United Nations sponsored Earth Summit held in Rio de Janeiro in 1992. The conference was held to attempt to reconcile worldwide economic development with the need to preserve the environment. Representatives of 178 nations attended, including 117 heads of state, making it the largest gathering of world leaders in history. Documents and treaties were signed committing most of the world's nations to the economic development in ways that were compatible with a healthy environment. A binding treaty called "The Framework Convention on Climate Change, or Global Warming Convention" was adopted, requiring nations to reduce emissions of greenhouse gases. The treaty failed to set binding targets for **emission** reductions, however. Agreement was hampered by discord between industrialized nations of western Europe, and North America and developing nations in Africa, Latin America, the Middle East and Asia. Developing countries were concerned that environmental restrictions would hamper economic growth unless they received increased aid from devel-

oped nations to enable them to grow in an environmentally sound way.

National and regional efforts to limit greenhouse gas has been most evident in western Europe, although disagreements between countries have prevented a unified approach among members of the European Community (EC). Britain has refused to accept a proposed carbon and energy tax, favored by several nations. Spokesmen for Britain expressed doubt that the tax would achieve desired reductions, and claimed that the two-thirds reduction in emissions to which Britain was committed would result from a planned enactment of a value-added tax (VAT) on fuel and energy. Critics of Britain's position argued that their plan was not sufficiently focused because it did not specially target fuels that increase atmospheric carbon dioxide. A 1996 report from the European Environmental Agency (EEA) in Copenhagen concluded that "green taxes" adopted by individual European countries in the last decade have been successful. So-called **green taxes** are a variety of environmentally friendly tax measures intended to reduce **pollution** and toxic wastes and encourage efficient resource use. Carbon taxes, such as those enacted in Norway and Sweden in 1991, are one example. Other examples include taxes on sulfur and **nitrogen** oxide emissions, **water pollution** charges, and charges for **household waste**. The carbon dioxide tax in Norway was reported to have reduced CO_2 emissions by 3–4%. The goal in the Scandinavian countries and the Netherlands has been to move away from taxes on labor or capital to those on **energy and the environment**. The consensus in western Europe seems to be that current environmental policies are weighted too much in the direction of regulation, and that there is a need to provide economic incentives in the form of well-designed environmental taxes.

Although eastern European countries have moved forward more slowly than in the rest of the continent, Poland, Hungary, and Estonia are beginning to adopt environmental charges and taxes. In the far-east, the Japanese Environmental Agency has reported that Japan might be able to keep per capita emissions of carbon dioxide at 1990 levels, which would result in a small increase in total emissions because of **population growth**.

The effectiveness of green taxes, including carbon taxes, is not universally accepted. Some argue that goals need to be defined more carefully with specified amounts or percentages of reduction in targeted pollutants. The EEA report acknowledges that the evaluation of the effectiveness is difficult and that, "Judgments about the performance of green taxes remain at the level of best guesses." Although theoretical evaluation of environmental taxation is well-developed, adequate evaluation of practical experience with such taxes is still relatively rare. Proper evaluation must separate the effects of green taxes from other factors, and assess what would have happened without the taxes. It is also recognized that it may take as much as a decade for a tax to have the desired effect.

In the United States, the Clinton administration, in 1993, published a 50-point plan to reduce greenhouse gas emissions by 100 million tons through a number of voluntary measures. Among the steps recommended were greater **energy efficiency** in homes and electrical appliances, reduced emissions from **power plants**, greater reliance on hydroelectric power, and increased tree planting. Some observers believe that the prospects for "green taxes" are less favorable in the United States than in Europe because of difficulty of passing legislation through two houses of Congress, which may be controlled by different parties, and obtaining approval by the president. Some individual states, however, have enacted measures that create economic incentives for environmental protection. Louisiana, which has many **petrochemical** companies within its borders, created an "environmental scorecard" in 1991, to keep a tally of companies' toxic discharges, waste volumes, and compliance with environmental laws. Graded exemptions from property taxes are granted to companies with good scores. Oregon's Energy Facility Siting Task Force recommended establishment of a standard to reduce emissions of carbon dioxide, with provisions for offsets for planting trees (which remove CO_2 from the air), and for the use of **renewable energy** sources.

Carcinogen

A carcinogen is any substance or agent that produces or induces the development of **cancer**. Carcinogens are known to affect and initiate metabolic processes at the level of cellular DNA.

Cancer accounts for slightly over 20% of all deaths each year. It is estimated that one out of every four Americans will develop cancer eventually and that six out of 10 in this group will die from the disease itself or complications arising from the disease. Half of all cancer deaths occur before the age of 65. Among women between 30 and 40 and children between three and 14, cancer is the leading cause of death next to accidents. It is the most frequent cause of death among Americans under 35 years of age.

The testing of **chemicals** as cancer-producing agents began with the observation of Sir Percival Pott in 1775 that scrotal cancer in young chimney sweeps resulted from the lodgement of soot in the folds of their scrotums. Pott was the first to link an environmental agent, **coal** tar, to cancer growth. In 1918 scientists began to test chemical derivatives for their cancer-causing efficacy. These first experiments looked at polycyclic **hydrocarbons**, specifically benzo(a)-pyrene found in coal tar, and they demonstrated that a certain degree of exposure to coal tar produced cancer in laboratory rats. In 1908, Vilhelm Ellerman and Oluf Bang of Denmark reported that an infectious agent could cause cancer, after they found that a leukemia-like blood disease was transmitted among domestic fowl via a **virus**. In 1911, Peyton Rous established a viral cause for a cancer called sarcoma in domestic fowl, and he was awarded a Nobel Prize for this discovery some 55 years later. In 1932, Lacassagne reported that estrogen injections caused mammary cancer in mice. This opened up investigation into the role hormones played in the development of various types of cancers.

In 1896, Wilhelm Roentgen discovered the x ray, a radioactive **emission** capable of penetrating many solid materials including the human body. x rays quickly found use as a diagnostic tool in medicine; but operators of x ray devices, unaware of their harmful effects, determined the proper intensity of the beams by repeatedly exposing their hands to the rays. Many operators of x ray equipment began to suffer from cancer of the hand, and Roentgen himself died of cancer. The most dramatic environmental link to cancer induced by **radioactivity** was observed after the bombing of **Hiroshima, Japan** when there was a radical increase in **leukemia** type cancers among people exposed to the atomic blast.

Environmental agents such as toxic chemicals and radiation are considered responsible for about 85% of all cancer cases. A great many environmental agents such as synthetic chemicals, sunlight (exposure to UV and UVB rays), air pollutants, **heavy metals**, x rays, high-fat diet, chemical pesticides, and cigarette smoking are known to be carcinogenic. Surveys carried out on the geographic incidence of cancer indicate that certain types of cancer are far more common in heavily industrialized areas. New Jersey, the site of approximately 1,200 chemical plants and related industries, has the highest overall cancer rate in the United States.

Tobacco use, particularly cigarette smoking, is now recognized as the leading contributor to cancer **mortality** in the United States. Currently one third of all cancer deaths are due to lung cancer, and of the 130,000 new lung cancer victims diagnosed each year, 80% are cigarette smokers. Several years ago, the primary cause of cancer among women was breast cancer—but by the late 1980s, lung cancer had surpassed breast cancer as the leading cause of death among women. Current controversy rages over the role of secondary **smoke** as a contributing cause of cancer among nonsmokers exposed to **cigarette smoke**.

Dietary factors have been extensively investigated, and experiments have implicated everything from coffee to charcoal broiled meat to peanut butter as possible carcinogens. A major concern among meat producers was the use of diethylstilbestrol (DES) as a source for beefing up cattle. DES is a synthetic hormone that increases the rate of growth in cattle. In the 1960s, DES was fed to about three fourths of all the cattle raised in the United States. It was also used to prevent miscarriages in women until 1966, when it was shown to be carcinogenic in mice. DES is now linked to vaginal and cervical cancers in women born between 1950 and 1966 whose mothers took DES during their pregnancies.

In 1971, DES was banned for use in cattle by the **Food and Drug Administration** (FDA), but the federal courts reversed the ban, contending that DES posed no danger since it was not directly added to foods but was administered only to cattle. When the FDA subsequently showed that measurable quantities remained present in slaughtered cattle, the courts reinstated the ban. But the issue of using growth additives in meat production remains unresolved today. Environmentalists are still concerned that known carcinogenic chemicals used to "beef up" cattle are being consumed by humans in various meat products, though no direct links have yet been established. In addition, various **food additives**, such as coal tar dyes used for artificial coloring and food preservatives, have produced cancer in laboratory animals. As yet there is no evidence indicating that human cancer rates are rising because of these substances in food.

Air pollution has been extensively investigated as a possible carcinogen and it is known that people living in cities larger than 50,000 run a 33% higher risk of developing lung cancer than people who live in other areas. The reasons behind this phenomenon, referred to as the "urban factor," have never been conclusively determined. Areas with populations exceeding 50,000 tend to have more industry, and air pollutants can have a profound effect in regions such as New Jersey where they are highly concentrated.

Occupational exposure to carcinogenic substances accounts for an estimated 2–8% of diagnosed cancers in the United States. Until passage of the Toxic Substances Control Act in 1976, which gave the federal government the power to require testing of potentially hazardous substances before they go on the market, hundreds of new chemicals with unknown side effects came into industrial use each year. Substances such as **asbestos** are estimated to cause 30–40% of all deaths among workers who have been exposed to it. **Vinyl chloride**, a basic ingredient in the production of

plastics, was found in 1974 to induce a rare form of liver cancer among exposed workers. Anaesthetic gases used in operating rooms have been traced as the reason nurse anesthetists develop leukemia and lymphoma at three times the normal rate with an associated higher rate of miscarriage and **birth defects** among their children. **Benzene**, an industrial chemical long known as a bone-marrow poison, has been shown to induce leukemia as well. A major step forward in the regulation of these potential cancer causing agents is the implementation by the Occupational Safety and Health Administrations (OSHA) of the Hazard Communication Standard in 1983, intended to provide employees in manufacturing industries access to information concerning hazardous chemicals encountered in the workplace.

With the **erosion** of the **ozone** layer of our **atmosphere**, increased concern about over-exposure to **ultraviolet radiation** and its subsequent effect on the formation of skin cancer has developed. The EPA estimates that a five% ozone depletion in the **stratosphere** would result in a substantial increase in a variety of skin cancers. This would include an average of two million extra cases of basal-cell and squamous-cell skin cancers a year and an additional 30,000 cases of the often fatal melanoma skin cancer, which currently kills 9,000 Americans per year. *See also* Hazardous waste siting; Love Canal, New York; Ozone layer depletion; Radiation exposure; Radiation sickness; Radon; Toxic substance

Carrying capacity

Carrying capacity is a general concept based on the idea that every **ecosystem** has a limit for use that cannot be exceeded without damaging the system. Whatever the specified use of an area might be, whether for grazing, **wildlife habitat**, **recreation**, or economic development, there is a threshold that cannot be breached, except temporarily, without degrading the ability of the **environment** to support that use. Examinations of carrying capacity attempt to determine, with varying degrees of **accuracy**, where this threshold lies and what the consequences of exceeding it might be.

The concept of carrying capacity was pioneered early this century in studies of range management and **wildlife management**. Range surveys of what was then called "grazing capacity" were carried out on the Kaibab Plateau in Arizona as early as 1911, and this term was used in most of the early bulletins issued by the **U.S. Department of Agriculture** on the subject. In his 1923 classic, *Range and Pasture Management,* Sampson defined grazing capacity as "the number of stock of one or more classes which the area will support in good condition during the time that the forage is palatable and accessible, without decreasing the forage production in subsequent seasons." Sampson was quick to point out that the "grazing capacity equation has not been worked out on any range unit with mathematical precision." In fact, because of the number of variables involved, especially variables stemming from human actions, he did not believe that the "grazing-capacity factor will ever be worked out to a high degree of scientific accuracy." Sampson also pointed out that "grazing the pasture to its very maximum year after year can produce only one result—a sharp decline in its carrying capacity," and he criticized the stocking of lands at their maximum instead of their optimum capacity. Similar discussions of carrying capacity can be found in books about wildlife management from the same period, particularly *Game Management* by **Aldo Leopold**, published in 1933.

Practitioners of applied **ecology** have calculated the number of animal-unit months that any given land area can carry over any given period of time. But there have been some controversies over the application of the concept of carrying capacity. The concept is commonly employed without considering the factor of time, neglecting the fact that carrying capacity refers to **land use** that is sustainable. Another common mistake is to confuse or ignore the implicit distinctions between maximum, minimum, and optimum capacity. In discussions of land use and environmental impact, some officials have drawn graphs with curves showing maximum use of an area and claimed that these figures represent carrying capacity. Such representations are misleading because they assume a perfectly controlled population, one without fluctuation, which is not likely. In addition, the maximum allowable population can almost never be the carrying capacity of an area, because such a number can almost never be sustained under all possible conditions. A population in balance with the environment will usually fluctuate around a mean, higher or lower, depending on seasonal habitat conditions, including factors critical to the support of that particular **species** or community.

The concept of carrying capacity has important ramifications for **human ecology** and **population growth**. Many

of the essential systems on which humans depend for sustenance are showing signs of stress, yet demands on these systems are constantly increasing. William R. Catton has formulated an important axiom for carrying capacity: "For any use of any environment there is a use intensity that cannot be exceeded without reducing that environment's suitability for that use." He then defined carrying capacity for humans on the basis of this axiom: "The maximum human population equipped with a given assortment of technologies and a given pattern of organization that a particular environment can support indefinitely."

The concept of carrying capacity is the foundation for recent interest in **sustainable development**, an environmental approach which identifies thresholds for economic growth and increases in human population. Sustainable development calculates the carrying capacity of the environment based on the size of the population, the standard of living desired, the overall quality of life, the quantity and type of artifacts created, and the demand on energy and other resources. With his calculations on sustainable development in Paraguay, Herman Daly has illustrated that it is possible to work out rough estimates of carrying capacity for some human populations in certain areas. He based his figures on the ecological differences between the country's two major regions, as well as on differences among types of settlers, and differences between developed good land and undeveloped marginal lands.

If ecological as well as economic and social factors are taken into consideration, then any given environment has an identifiable tolerance for human use and development, even if that number is not now known. For this reason, many environmentalists argue that carrying capacity should always be the basis for what has been called "demographic accounting."

Rachel Louise Carson (1907 – 1964)

American ecologist, marine biologist, and writer

Rachel Louise Carson was a university-trained biologist, a longtime United States government employee, and a best-selling author of such books as *Edge of the Sea*, *The Sea Around Us* (a National Book Award winner), and *Silent Spring*.

Her book on the dangers of misusing pesticides, *Silent Spring*, has become a classic of environmental literature and resulted in her recognition as the fountainhead of modern **environmentalism**. *Silent Spring* was reissued in a twenty-fifth anniversary edition in 1987, and remains standard reading for anyone concerned about environmental issues.

Carson grew up in the Pennsylvania countryside and reportedly developed an early interest in **nature** from her mother and from exploring the woods and fields around her home. She was first an English major in college, but a required course in biology rekindled that early interest in the subject and she graduated in 1928 from Pennsylvania College for Women with a degree in zoology and went on to earn a master's degree at Johns Hopkins University. After the publication of *Silent Spring*, she was often criticized for being a "popular science writer" rather than a trained biologist, making it obvious that her critics were unaware of her university work, including a master's thesis entitled "The Development of the Pronephros During the Embryonic and Early Larval Life of the Catfish (*Ictalurus punctatus*)."

Summer work also included biological studies at Woods Hole Marine Biological Laboratory in Massachusetts, where she became more interested in the life of the sea. After doing a stint as a part-time scriptwriter for the Bureau of Fisheries, she was hired full-time as a junior aquatic biologist. When she resigned from the United States **Fish and Wildlife Service** in 1952 to devote her time to her writing, she was biologist and chief editor there. First, as a biologist and writer with the Bureau and then as a free-lance writer and biologist, she successfully combined professionally the two great loves of her life, biology and writing.

Often described as "a book about death which exalts life," *Silent Spring* is the work on which Carson's position as the modern catalyst of a renewed environmental movement rests. The book begins with a shocking fable of one composite town's "silent spring" after pesticides have decimated insects and the birds that feed upon them. The main part of the book is a massive documentation of the effects of organic pesticides on all kinds of life, including birds and

humans. The final sections are quite restrained, drawing a hopeful picture of the future, if feasible alternatives to the use of pesticides—such as biological controls—are used in conjunction with and as a partial replacement of chemical sprays.

Carson was quite conservative throughout the book, being careful to limit examples to those that could be verified and defended. In fact, there was very little new in the book; it was all available earlier in a variety of scientific publications. But her science background allowed her to judge the credibility of the facts she uncovered and provided sufficient knowledge to synthesize a large amount of data. Her literary skills made that data accessible to the general public.

Silent Spring was not a polemic against all use of pesticides but a reasoned argument that potential hazards be carefully and sufficiently considered before any such chemical was approved for use. Many people date modern concern with environmental issues from her argument in this book that "future generations are unlikely to condone our lack of prudent concern for the integrity of the natural world that supports all life." It is not an accident that her book is dedicated to **Albert Schweitzer**, because she wrote it from a shared philosophy of reverence for life.

Carson provided an early outline of the potential of using biological controls in place of **chemicals**, or in concert with smaller doses of chemicals, an approach now called **integrated pest management**. She worried that too many specialists were concerned only about the effectiveness of chemicals in destroying pests and "the overall picture" was being lost, in fact not valued or even sought. She pointed out the false safety of assuming that products considered individually were safe, when in concert, or synergistically, they could lead to human health problems.

Her **holistic approach** was one of the real, and unusual, strengths of the book. Prior to the publication of *Silent Spring*, she even refused to appear on a **National Audubon Society** panel on pesticides because such an appearance could provide a forum for only part of the picture and she wanted her material to first appear "as a whole." She did allow it to be partially serialized in *The New Yorker*, but articles in that magazine are long and detailed.

The book was criticized early and often, and often viciously and unfairly. One chemical company, reacting to that pre-publication serialization, tried to get Houghton Mifflin not to publish the book, citing Carson as one of the "sinister influences" trying to reduce the use of **agricultural chemicals** so that United States food supplies would dwindle to the level of a developing nation. The chemical industry apparently united against Carson, distributing critical reviews and threatening to withdraw magazine advertisements from journals deemed friendly to her. Words and phrases used in the attacks included "ignorant," "biased," "sensational," "unfounded," "distorted," "not written by a scientist," "littered with crass assumptions and gross misinterpretations," to name but a few.

Some balanced reviews were also published, most noteworthy one by Cornell University ecologist LaMont Cole in *Scientific American*. Cole identified errors in her book, but finished by saying "errors of fact are so infrequent, trivial and irrelevant to the main theme that it would be ungallant to dwell on them," and went on to suggest that the book be widely read in the hopes that it "may help us toward a much needed reappraisal of current policies and practices." That was the spirit in which Carson wrote *Silent Spring* and reappraisals and new policies were indeed the result of the myriad of reassessments and studies spawned by its publication. To its credit, it did not take the science community long to recognize her credibility; the President's Science Advisory Committee issued a 1963 report that the journal *Science* suggested "adds up to a fairly thorough-going vindication of Rachel Carson's *Silent Spring* thesis."

While it is important to recognize the importance of *Silent Spring* as a landmark in the environmental movement, one should not neglect the significance of her other work, especially her three books on oceans and marine life and the impact of her writing on people's awareness of one of earth's great natural ecosystems.

Under the Sea Wind (1941) was Carson's attempt "to make the sea and its life as vivid a reality [for her readers] as it has become for me." And readers are given vivid narratives about the shore, including vegetation and birds, on the open sea, especially by tracing the movements of the mackerel, and on the sea bottom, again by focusing on an example, this time the eel. *The Sea Around Us* (1951) continues Carson's treatment of marine biology, adding an account of the history and development of the sea and its physical features such as islands and tides. She also includes human perceptions of and relationships with the sea. *The Edge of the Sea* (1955) was written as a popular guide to beaches and sea shores, but focusing on rocky shores, sand beaches, and coral and mangrove coasts, it complemented the physical descriptions in *The Sea Around Us* with biological data.

Carson was a careful and thorough scientist, an inspiring author, and a pioneering environmentalist. Her groundbreaking book, and the controversy it generated, was the catalyst for much more serious and detailed looks at environmental issues, including increased governmental investigation that led to creation of the **Environmental Protection Agency** (EPA). Her work will remain a hallmark in the increasing awareness modern people are gaining of how humans interact with and impact the **environment** in which they live and on which they depend.

Cash crop

A crop that is produced for the purpose of exporting or selling rather than for consumption by the person who grows it. In many **Third World** countries, cash crops often replace the production of basic food staples such as rice, wheat, or corn in order to generate foreign exchange. For example, in Guatemala, much of the land is devoted to the production of bananas and citrus fruits (97% of the citrus crop is exported), which means that majority of the basic food products needed by the native people are imported from other countries. Often these foods are expensive and difficult for many poor people to obtain. Cash crop agriculture also forces many subsistence and tenant farmers to give up their land in order to make room for industrialized farming.

Catalytic converter

Catalytic converters are devices which employ a catalyst to facilitate a chemical reaction. (A catalyst is a substance that changes the rate of a chemical reaction, but whose own composition is unchanged by that reaction.) For **air pollution control** purposes, such reactions involve the reduction of nitric oxide to molecular oxygen and **nitrogen** or oxidation of **hydrocarbons** and **carbon monoxide** to **carbon dioxide** and water. Using the catalyst, the activation energy of the desired chemical reaction is lowered. Therefore, exothermic chemical conversion will be favored at a lower temperature.

Traditional catalysts have normally been metallic, although nonmetallic materials, such as ceramics, have been coming into use in recent years. Metals used as catalysts may include noble metals, such as platinum, or **base** metals, including **nickel** and **copper**. Some catalysts are more effective in oxidation, others are more effective in reduction. Some metals are effective in both kinds of reactions. The catalyst material is normally coated on a porous, inert support structure of varying design. Examples include honeycomb ceramic structures with long channels and pellet beds. The goal is to channel exhaust over a large surface area of catalyst without an unacceptable pressure drop.

In some cases, reduction and oxidation catalysts are combined to control oxides of nitric oxide, **carbon** monoxide, and hydrocarbon emissions in exhaust from internal **combustion** engines. The reduction and oxidation processes can be conducted sequentially or simultaneously. Dual catalysts are used in sequential reduction-oxidation. In this case, the exhaust gas from a rich-burn engine initially enters the reducing catalyst to reduce nitric oxide. Subsequently, as the exhaust enters an oxidation catalyst, it is diluted with air to provide oxygen for oxidation. Alternatively, three-way catalysts can be used for simultaneous reduction and oxidation. Engines exhausting to such catalysts run slightly rich and require tight regulation of air-fuel ratio.

A catalytic converter at a large petrochemical plant. (Phototgraph by Tom Carroll. Phototake. Reproduced by permission.)

Reducing catalysts can be made more efficient using a reducing agent, such as ammonia. This method of control, referred to as selective catalytic reduction, has been employed successfully on large turbines. In this case, a reducing agent is introduced upstream of a reducing catalyst, allowing for greater rates of nitric oxide reduction.

Catskill Watershed Protection Plan

New York City has long been proud of its excellent municipal drinking water. Approximately 90% of that water comes from the Catskill/Delaware **Watershed**, which covers about 1,900 square miles (nearly 5,000 square kilometers) of rugged, densely forested land north of the city and west of the **Hudson River**. Stored in six hard-rock reservoirs and transported through enormous underground tunnels, the city water is outstanding for so large an urban area. Yielding 1.2 billion gal (450,000 cubic meters) per day, and serving more than 9 million people, this is the largest surface water storage and supply complex in the world. As the metropolitan **agglomeration** has expended, however, people have moved into the area around the Catskill Forest Preserve, and **water quality** is not as high as it was a century ago.

When the 1986 U.S. **Safe Drinking Water Act** mandated **filtration** of all public surface water systems, the city was faced with building an $8 billion **water treatment** plant that would cost up to $500 million per year to operate. In 1989, however, the **Environmental Protection Agency** (EPA) ruled that the city could avoid filtration if it could meet certain minimum standards for microbial contaminants such as bacteria, viruses, and protozoan **parasites**. In an attempt to limit pathogens and nutrients contaminating surface water and to avoid the enormous cost of filtration, the city proposed land-use regulations for the five counties (Green, Ulster, Sullivan, Schoharie, and Delaware) in the

Catskill/Delaware watershed from which it draws most of its water.

With a population of 50,000 people, the private land within the 200 square mi (520 square km) watershed is mostly devoted to forestry and small dairy farms, neither of which are highly profitable. Among the changes the city called for was elimination of storm water **runoff** from barnyards, **feedlots**, or grazing areas into watersheds. In addition, farmers would be required to reduce **erosion** and surface runoff from crop fields and **logging** operations. Property owners objected strenuously to what they regarded as onerous burdens that would cost enough to put many of them out of business. They also bristled at having the huge megalopolis impose rules on them. It looked like a long and bitter battle would be fought through the courts and the state legislature.

To avoid confrontation, a joint urban/rural task force was set up to see if a compromise could be reached, and to propose alternative solutions to protect both the water supply and the long-term viability of agriculture in the region. The task force agreed that agriculture is the "preferred land use" on private land, and that agriculture has "significant present and future environmental benefits." In addition, the task force proposed a voluntary, locally developed and administered program of "whole farm planning and best management approaches" very similar to ecosystem-based, **adaptive management**.

This grass-roots program, financed mainly by the city, but administered by local farmers themselves, attempts to educate landowners, and provides alternative marketing opportunities that help protect the watershed. Economic incentives are offered to encourage farmers and foresters to protect the water supply. Collecting feedlot and barnyard runoff in **infiltration** ponds together with solid **conservation** practices such as **terracing**, **contour plowing**, strip farming, leaving crop residue on fields, ground cover on waterways, and cultivation of perennial crops such as orchards and sugarbush have significantly improved watershed water quality. As of 1999, about 400 farmers—close to the 85% participation goal—have signed up for the program. The cost, so far, to the city has been about $50 million—or less than 1% of constructing a treatment plant.

In addition to saving billions of dollars, this innovative program has helped create good will between the city and its neighbors. It has shown that upstream cleanup, prevention, and protection are cheaper and more effective than treating water after it's dirty. Farmers have learned they can be part of the solution, not just part of the problem. This experiment serves as an excellent example of how watershed planning through cooperation is effective when local people are given a voice and encouraged to participate.

Center for Environmental Philosophy

The Center for Environmental Philosophy was established in 1989 as an organization dedicated to furthering research, publication, and education in the area of environmental philosophy and ethics. Based at the University of North Texas since 1990, the primary activities of the center are the publication of the journal *Environmental Ethics*, the reprinting of significant books on **environmental ethics** under its own imprint, the sponsorship of various workshops and conferences dedicated to the furthering of research and training in environmental ethics, and the promotion of graduate education, postdoctoral research, and professional development in the field of environmental ethics.

The Center is best known for its journal, which virtually established the field of environmental ethics and remains perhaps the leading forum for serious philosophical work in environmental philosophy. Inspired in part by Aldo Leopold's contention in "A Sand County Almanac" that the roots of most ecological problems were philosophical, Eugene C. Hargrove founded *Environmental Ethics* in 1978. The journal was originally concerned primarily with whether the attribution of rights to animals and to **nature** itself could be coherently defended as a philosophical doctrine. While remaining true to its central preoccupation with ethics, the journal's interests have more recently broadened to include significant essays on such topics as **deep ecology**, **ecofeminism**, **social ecology**, economics, and public policy. Under Hargrove's editorial leadership, the journal has brought environmental ethics to increasing acceptance as a serious field by mainstream academic philosophers. *Environmental Ethics* also is now widely read by researchers concerned with the **environment** in the fields of biological science, economics, and policy science. It also is developing a small but growing following among environmental professionals such as **conservation** biologists.

The Center also helps to sponsor, in conjunction with the Department of Philosophy and Religious Studies at the

University of North Texas, programs in which graduate students may take courses and specialize in the field of environmental ethics.

Center for Respect of Life and Environment

Formed in 1986, the Center for Respect of Life and **Environment** (CRLE) is a nonprofit group based in Washington, D.C., that works to promote humane and **environmental ethics**, particularly within the academic and religious communities with an emphasis on the links between **ecology**, spirituality, and sustainability.

CRLE describes itself as being committed to "encourage the well-being of life and living systems—plant, animal, and human relationships..." The work of the Center is "to awaken the public's ecological sensibilities, and to transform lifestyles, institutional practices, and social policies to support the community of life..." In order to accomplish these goals, CRLE sponsors conferences of professionals and experts in various fields and puts out a variety of publications, including a quarterly journal, *Earth Ethics*.

Through workshops and conferences, CRLE's Higher Education Project brings together educators from various institutions to discuss greening policies. The Center's Greening of Academia program works with colleges and universities to make the academic curricula, food services, and other campus policies "ecologically sound, socially just, and humane." CRLE also publishes a *Green Guide to Higher Education*, which describes the availability and ecological orientation of courses at various institutions of higher learning.

The Center's Religion in the Ecological Age program focuses on "ecospirituality," stressing that today's religious leaders and institutions must take the responsibility for addressing the issues of environmental justice, the human population explosion, over-consumption of **natural resources**, and other environmental problems that threaten the well-being of the natural environment and of the humans and **wildlife** dependent on it. CRLE sponsors conferences and publications on such issues, including a series of international conferences in Assisi, Italy (home of St. Francis of Assisi, the thirteenth century lover of animals and patron saint of **nature**).

Fundamental to the Center's mission was the creation of an **Earth Charter**. The Charter was approved by the Earth Charter Commission in 2000 and hopefully will be backed by the United Nations in 2002. It will "prescribe new norms for state and interstate behavior needed to maintain livelihoods and life on our shared planet." CRLE says that the main purpose of the Earth Charter is to "create a 'soft law' document that sets forth the fundamental principles of this emerging new ethics, principles that include respect for human rights, peace, economic equity, environmental protection and sustainable living... It is hoped that the Charter will become a universal code of conduct for states and people..."

Other activities of the Global Earth Ethic project include sponsoring conferences and publications focusing on ethics as they relate to agriculture, development, the environment, and "the appropriate use of animals in research, education, and agriculture..." This effort to raise consciousness includes a three-year project focused on establishing a new principle for agriculture explained in the "Soul of Agriculture: a Production Ethic for the 21st Century."

CRLE's Sustainable Livelihoods in Sustainable Communities program works with United Nations agencies and other regional and international organizations to promote environmentally sustainable developmental and agricultural practices through publications, conferences and meetings, with particular emphasis on **indigenous peoples** and rural communities.

CRLE's quarterly journal, *Earth Ethics*, offers book reviews and a calendar of upcoming events, and it provides a forum for scholarly and provocative feature articles discussing and debating sustainability and other environmental topics as they affect the fields of religion, agriculture, education, business, and the arts, often "challenging current economic and developmental practices."

The Center is affiliated with and supported by the **Humane Society of the United States**, the nation's largest animal protection organization.

Center for Rural Affairs

The Center for Rural Affairs (CRA) is a nonprofit organization dedicated to the social, economic and **environmental health** of rural communities. Founded in 1973, the Center for Rural Affairs includes among its participants farmers, ranchers, business people, and educators concerned with the decline of the family farm.

CRA works to provoke public thought on issues and government policies that affect rural Americans, especially in the Midwest and Plains regions of the country. It sponsors research, education, advocacy, organizing and service projects aimed to improve the life of rural dwellers. CRA's **sustainable agriculture** policy is designed to analyze, propose, and advocate public policies that reward environmental stewardship, promote family farming, and foster responsible technology. CRA assists beginning farmers with design and implement on-site research that helps to make these farms environmentally sound and economically viable. CRA's **conservation** and education programs address the environmental problems caused by agricultural practices in the North Central United States.

Through a rural enterprise assistance program, CRA teaches rural communities to support self-employment, and it provides business assistance and revolving loan funds for the self-employed. It also provides professional farm management and brokerage service to landowners who are willing to rent or sell land to beginning farmers. CRA promotes fair competition in the agriculture marketplace by working to prevent monopolies, encouraging enforcement of laws restricting corporate farming in the United States, and advocating for the role of United States farmers in international markets.

Publications offered by CRA include the *Center for Rural Affairs Newsletter*, a monthly report on policy issues and research findings; the *Rural Enterprise Reporter*, which provides information about developing small local enterprises; and a variety of special reports on topics such as small farm technology and business strategy.

Center for Science in the Public Interest

The Center for Science in the Public Interest (CSPI) was founded in 1971 by Michael Jacobson, who remains its executive director. It is a consumer advocacy organization principally concerned with nutrition and food safety, and its membership consists of scientists, nutrition educators, journalists, and lawyers.

CSPI has campaigned on a variety of health and nutrition issues, particularly nutritional problems on a national level. It is the purpose of the group to address "deceptive marketing practices, dangerous **food additives** or contaminants, conflicts of interests in the academic community, and flawed science propagated by industries concerned solely with profits." It monitors current research on nutrition and food safety, as well as the federal agencies responsible for these areas. CSPI maintains an office for legal affairs and special projects. It has initiated legal actions to restrict food contaminants and to ban food additives that are either unsafe or poorly tested. The special projects the group has sponsored include: Americans for Safe Food, the Nutrition Project, and the Alcohol Policies Project. The center publishes educational materials on food and nutrition, and it works to influence policy decisions affecting health and the national diet.

CSPI has made a significant impact on food marketing in the past 10 years, and they have successfully contested food labeling practices in many sectors of the industry. They were instrumental in forcing fast-food companies to disclose ingredients, and they have recently pressed the **Food and Drug Administration** to improve regulations for companies which make and distribute fruit juice. Many brands do not reveal the actual percentages of the different juices used to make them, and certain combinations of juices are often misleadingly labeled as cherry juice or kiwi juice, for instance, when they may be little more than a mixture of apple and grape juice. The organization has also taken action against deceptive food advertising, particularly advertising for children's products. It has recently demanded further testing of a sweetener called sucralose, in the wake of studies that have suggested that it could cause shrinkage of the thymus, a gland affecting cellular immune responses.

CSPI is funded mainly by foundation grants and subscriptions to its *Nutrition Action Newsletter*. The newsletter is published ten months out of the year and is intended to

increase public understanding of food safety and nutrition issues. It frequently examines the consequences of legislation and regulation at the state and federal level; it has explored the controversy over organic and chemical farming methods, and it has studied how agribusiness has changed the way Americans eat. CSPI also distributes posters, videos, and computer software, and it offers a directory of mail-order sources for organically-grown food. Its brochures and reports include: *Guess What's Coming to Dinner: Contaminants in Our Food* and *Organic Agriculture: What the States Are Doing*. It has a staff of 45, a membership of 800,000, and an annual budget of $10,000,000.

Centers for Disease Control and Prevention

The Centers for Disease Control and Prevention (CDC) is the Atlanta, Georgia-based agency of the **Public Health Service** that has led efforts to prevent diseases such as **malaria**, polio, smallpox, tuberculosis, and acquired immunodeficiency syndrome (**AIDS**). As the nation's prevention agency, the CDC's responsibilities have expanded, and it now addresses contemporary threats to health such as injury, environmental and occupational hazards, behavioral risks, and chronic diseases.

Divisions within the CDC use surveillance, epidemiologic and laboratory studies, and community interventions to investigate and prevent public health threats.

The Center for Chronic Disease Prevention and Health Promotion designs programs to reduce death and disability from chronic diseases—cardiovascular, kidney, liver and lung diseases, and **cancer** and diabetes.

The Center for Environmental Health and Injury Control assists public health officials at the scene of natural or artificial disasters such as **volcano** eruptions, forest fires, hazardous **chemical spills**, and nuclear accidents. Scientists study the effects of **chemicals** and pesticides, reactor accidents, and health threats from **radon**, among others. The National Institute for Occupational Safety and Health helps identify chemical and physical hazards that lead to occupational diseases.

Preventing and controlling infectious diseases has been a goal of the CDC since its inception in 1946. The Center for Infectious Diseases investigates outbreaks of infectious disease locally and internationally. The Center for Prevention Services provides financial and technical assistance to control and prevent diseases. Disease detectives in the **Epidemiology** Program Office investigate outbreaks around the world.

Prevention of **tobacco** use is a critical health issue for CDC because cigarette smoking is the leading preventable cause of death in this country. The Office on Smoking and Health conducts research on the effects of smoking, develops health promotion and education campaigns, and helps health departments with smoking education programs.

CDC researchers have improved technology for lead **poisoning** screening, particularly in children. CDC evidence on environmental lead **pollution** was a key in **gasoline** lead content reduction requirements. The CDC also coordinated and directed health studies of **Love Canal**, New York, residents in the 1980s. The director of the CDC administers the **Agency for Toxic Substances and Disease Registry**, the public health agency created to protect the public from exposure to toxic substances in the **environment**. In 1990, CDC became responsible for energy-related epidemiologic research for the **U.S. Department of Energy** nuclear facilities. This includes studies of people who have been exposed to radiation from materials emitted to the air and water from plant operations.

The CDC today carries out an ever-widening agenda with studies on adolescent health, dental disease prevention, the epidemiology of violence, and categorizing and tracking birth abnormalities and infant **mortality**.

Cesium 137

A radioactive **isotope** of the metallic element cesium. Cesium-137 is one of the major products formed when **uranium** undergoes **nuclear fission**, as in a nuclear reactor or

A chain reaction. (Illustration by Laurence Lawson. (Reproduced by permission.)

nuclear weapons. During atmospheric testing of nuclear weapons after World War II, cesium-137 was a source of major concern to health scientists. Researchers found that the isotope settled to the ground, where it was absorbed by plants and eaten by animals, ultimately affecting humans. Once inside the human body, the isotope releases beta particles, which are carcinogens, teratogens, and mutagens. Large quantities of cesium-137 were released when the Chernobyl nuclear reactor exploded in 1986.

Chain reaction

A situation in which one action causes or initiates a similar action. In a nuclear chain reaction, for example, a **neutron** strikes a uranium-235 nucleus, causing the nucleus to undergo fission, which in turn produces a variety of products. Among these products is one or more neutrons. Thus, the particle needed to initiate this reaction (the neutron) is itself produced as a result of the reaction. Once begun, the reaction continues as long as uranium-235 nuclei are available. Nuclear chain reactions are important sources of fission and fusion energy.

Chaparral

Chaparral is an ecological community consisting of drought-resistant evergreen shrubs and small trees that are adapted to long, hot, dry summers and mild, rainy winters. The chaparral is found in five places on earth where there is a warm land mass and a cool ocean: southern California, the

Cape Town area of South Africa, the western tip of **Australia**, the west coast of South America, and the coastal areas of the Mediterranean in southern Europe. Total annual precipitation ranges between 15 and 40 inches per year, while annual temperatures range from 50–64.4 °F (10–18 °C). Droughts and fires, which are often set by lightning during the summer/autumn dry season, are common in the chaparral. In fact, because the release of minerals occurs as a result of fire, many chaparral plants grow best after a fire.

The chaparral may have many types of terrain, including flat plains, rocky hills, and mountain slopes. The word chaparral comes from the Spanish word *chaparro*, meaning a dry thicket of oak shrubs.

The plants and animals that live in the chaparral are adapted to the characteristic hot and dry climatic conditions. Most of the plants are less than 10 ft tall and have leathery leaves with thick cuticles that hold moisture. Many of the shrub **flora** are aromatic, contain flammable oils, and are adapted to periodic burns. Examples of chaparral plants include poison oak, scrub oak, pine, manzanita, chamise, yucca, and cacti. The animals are mainly grassland and **desert** types, including coyotes, jack rabbits, mule deer, rattlesnakes, mountain lions, kangaroo rats, foxes, bobcats, lizards, horned toads, praying mantis, honey bees, and ladybugs.

Chelate

A chemical compound in which one atom is enclosed within a larger cluster of atoms that surrounds it like an envelope. The term comes from the Greek word *chela*, meaning claw. Chelating agents—compounds that can form chelates with other atoms—have a wide variety of environmental applications. For example, the compound ethylenediaminetetraacetic **acid** (EDTA) is used to remove **lead** from the blood. EDTA molecules surround and bind to lead atoms, and the chelate is then excreted in the urine. EDTA can also be used to soften hard water by chelating the calcium and magnesium ions that cause hardness.

Chelyabinsk, Russia

Chelyabinsk is the name of a province and its capital city in west-central Russia. It covers an area of about 34,000 mi^2 (88,060 km^2) and has a population of about 3.6 million. Chelyabinsk city lies on the Miass River on the eastern side of the Ural Mountains. Its population in 1990 was about 1.2 million.

Chelyabinsk is best known today as the home of Mayak, a 77-mi^2 (200-km^2) complex where **nuclear weapons** were built for the former Soviet Union. Because of intentional policy decisions and accidental releases of radioactive materials, Mayak has been called the most polluted spot on Earth.

Virtually nothing was known about Mayak by the outside world, the Russian people, or even the residents of Chelyabinsk themselves until 1991. Then, under the new philosophy of *glasnost*, Soviet president Mikhail Gorbachev released a report on the complex. It listed 937 official cases of chronic **radiation sickness** among Chelyabinsk residents. Medical authorities believe that the actual number is many times larger.

The report also documented the secrecy with which the Soviet government shrouded its environmental problems at Mayak. Physicians were not even allowed to discuss the cause or nature of the radiation sickness. Instead, they had to refer to it as the "ABC disease."

Chelyabinsk's medical problems were apparently the result of three major "incidents" involving the release of radiation at Mayak. The first dated from the late 1940s to the mid-1950s, when **radioactive waste** from nuclear weapons research and development was dumped directly into the nearby Techa River. People downstream from Mayak were exposed to radiation levels 57 times greater than those at the better-known Chernobyl accident in 1986. The Gorbachev report admitted that 28,000 people received radiation doses of "medical consequence." Astonishingly, almost no one was evacuated from the area.

The second incident occurred in 1957, when a nuclear waste dump at Mayak exploded with a force equivalent to a five to 10 kiloton atomic bomb. The site had been constructed in 1953 as an alternative to simply disgorging radioactive wastes into the Techa. When the automatic cooling system failed, materials in the dump were heated to a temperature of 662°F (350°C). In the resulting explosion, 20 million curies of radiation were released, exposing 270,000 people to dangerous levels of **radioactivity**. Neither the Soviet Union nor the United States government, which had detected the accident, revealed the devastation at Mayak.

The third incident happened in 1967. In their search for ways to dispose of radioactive waste, officials at Mayak decided in 1951 to use Lake Karachay as a repository. They

realized that dumping into the Techa was not a satisfactory solution, and they hoped that Karachay—which has no natural outlet—would be a better choice.

Unfortunately, radioactive materials began **leaching** into the region's water supply almost immediately. Radiation was eventually detected as far as 2 mi (3 km) away. The 1967 disaster occurred when an unusually dry summer diminished the lake significantly. A layer of radioactive material, deposited on the newly exposed shoreline, was spread by strong winds that blew across the area. This released radiation equivalent to the amount contained in the first atomic bomb explosion over Hiroshima.

Chemical bond

A chemical bond is any force of attraction between two atoms strong enough to hold the atoms together for some period of time. At least five primary types of chemical bonds are known, ranging from very strong to very weak. They are covalent, ionic, metallic, and **hydrogen** bonds, and London forces.

In all cases, a chemical bond ultimately involves forces of attraction between the positively-charged nucleus of one atom and the negatively-charged electron of a second atom. Understanding the nature of chemical bonds has practical significance since the type of bonding found in a substance explains to a large extent the macroscopic properties of that substance.

An ionic bond is one in which one atom completely loses one or more electrons to a second atom. The first atom becomes a positively charged **ion** and the second, a negatively charged ion. The two ions are attracted to each other because of their opposite electrical charges.

In a covalent bond, two atoms share one or more pairs of electrons. For example, a hydrogen atom and a fluorine atom each donate a single electron to form a shared pair that constitutes a covalent bond between the two atoms. Both electrons in the shared pair orbit the nuclei of both atoms.

In most cases, covalent and ionic bonding occur in such a way as to satisfy the Law of Octaves. Essentially that law states that the most stable configuration for an atom is one in which the outer energy level of the atom contains eight electrons or, in the case of smaller atoms, two electrons.

Ionic and covalent bonds might appear to represent two distinct limits of electron exchange between atoms, one in which electrons are totally gained and lost (ionic bonding) and one in which electrons are shared (covalent bonding). In fact, most chemical bonds fall somewhere between these two extreme cases. In the hydrogen-fluorine example mentioned above, the fluorine nucleus is much larger than the hydrogen nucleus and, therefore, exerts a greater pull on the shared electron pair. The electrons spend more time in the vicinity of the fluorine nucleus and less time in the vicinity of the hydrogen nucleus. For this reason, the fluorine end of the bond is more negative than the hydrogen end, and the bond is said to be a polar covalent bond. A non-polar covalent bond is possible only between two atoms with equal attraction for electrons as, for example, between two atoms of the same element.

Metallic bonds are very different from ionic and covalent bonds in that they involve large numbers of atoms. The outer electrons of these atoms feel very little attraction to any one nucleus and are able, therefore, to move freely throughout the metal.

Hydrogen bonds are very weak forces of attraction between atoms with partial positive and negative charges. Hydrogen bonds are especially important in living organisms since they can be broken and reformed easily during biochemical changes.

London forces are the weakest of chemical bonds. They are forces of attraction between two uncharged molecules. The force appears to arise from the temporary shift of electrical charges within each molecule.

Chemical oxygen demand

Chemical oxygen demand (COD) is a measure of the ability of chemical reactions to oxidize matter in an aqueous system. The results are expressed in terms of oxygen so that they can be compared directly to the results of **biochemical oxygen demand** (BOD) testing. The test is performed by adding the oxidizing solution to a sample, boiling the mixture on

a refluxing apparatus for two hours and then titrating the amount of dichromate remaining after the refluxing period. The titration procedure involves adding ferrous ammonium sulfate (FAS), at a known normality, to reduce the remaining dichromate. The amount of dichromate reduced during the test—the initial amount minus the amount remaining at the end—is then expressed in terms of oxygen. The test has nothing to do with oxygen initially present or used. It is a measure of the demand of a solution or suspension for a strong oxidant. The oxidant will react with most organic materials and certain inorganic materials under the conditions of the test. For example, Fe^{2+} and Mn^{2+} will be oxidized for Fe^{3+} and Mn^{4+}, respectively, during the test.

Generally, the COD is larger than the BOD exerted over a five-day period (BOD_5), but there are exceptions in which **microbes** of the BOD test can oxidize materials that the COD reagents cannot. For a raw, domestic **wastewater**, the COD/BOD_5 ratio is in the area of 1.5–3.0/1.0. Higher ratios would indicate the presence of toxic, nonbiodegradable or less readily **biodegradable** materials.

The COD test is commonly used because it is a relatively short-term, precise test with few interferences. However, the spent solutions generated by the test are hazardous. The liquids are acidic, and contain chromium, silver, **mercury**, and perhaps other toxic materials in the sample tested. For this reason laboratories are doing fewer or smaller COD tests in which smaller amounts of the same reagents are used.

Chemical spills

Chemical spills are any accidental releases of synthetic **chemicals** that pose a risk to the **environment**.

Spills occur at any of the steps between the production of a chemical and its use. A railroad tank car may spring a leak; a pipe in a manufacturing plant may break; or an underground storage tank may corrode allowing its contents to escape into **groundwater**. These spills are often classified into four general categories: the release of a substance into a body of water; the release of a liquid on land; the release of a solid on land; and the release of a gas into the **atmosphere**. The purpose of this method of classification is to provide the basis for a systematic approach to the control of any type of chemical spill.

Some of the most famous chemical spills in history illustrate these general categories. For example, seven cars of a train carrying the **pesticide** metam sodium fell off the tracks near Dunsmuir, California, in August 1991, breaking open and releasing the chemicals into the Sacramento River. Plant and aquatic life for 43 mi (70 km) downriver died as a result of the accident. The pesticide eventually formed a band 225 ft (70 m) wide across Lake Shasta before it could be contained.

In 1983, the **Environmental Protection Agency** (EPA) purchased the whole town of **Times Beach**, Missouri, and relocated more than 2,200 residents because the land was so badly contaminated with highly toxic dioxins. The concentration of these compounds, a by-product of the production of herbicides, was more than a thousand times the maximum recommended level.

In December 1984, a cloud of poisonous gas escaped from a Union Carbide chemical plant in **Bhopal, India**. The plant produced the pesticide Sevin from a number of chemicals, many of which were toxic. The gas that accidentally escaped probably contained a highly toxic mixture of phosgene, methyl isocyanate (MIC), **chlorine**, **carbon monoxide**, and **hydrogen** cyanide, as well as other hazardous gases. The cloud spread over an area of more than 15 mi^2 (40 km^2), exposing more than 200,000 people to its dangers.

Chemists have now developed a sophisticated approach to the treatment of chemical spills, which involves one or more of five major steps: containment, physical treatment, chemical treatment, biological treatment, and disposal or destruction. **Soil** sealants, which can be used to prevent a liquid from sinking into the ground, are an example of containment. One of the most common methods of physical treatment is activated charcoal, because it has the ability to adsorb toxic substances on its surface, thus removing them from the environment. Chemical treatment is possible because many hazardous materials in a spill can be treated by adding some other chemical that will neutralize them, and biological treatment usually involves **microorganisms** that will attack and degrade a toxic chemical. Open burning, **deep-well injection**, and burial in a **landfill** are all methods of ultimate disposal.

Chemicals

The general public often construes the word "chemical" to mean a harmful synthetic substance. In fact, however, the term applies to any element or compound, either natural or synthetic. The thousands of compounds that make up the human body are all chemicals, as are the products of scientific research. A more accurate description, however, can be found in the dictionary. Thus, aspirin is a chemical by this definition, since it is the product of a series of chemical reactions.

The story of chemicals began with the rise of human society. Indeed, early stages of human history, such as the Iron, **Copper**, and Bronze Ages reflect humans' ability to produce important new materials. In the first two eras, people learned how to purify and use pure metals. In the third case, they discovered how to combine two to make an alloy with distinctive properties.

The history of ancient civilizations is filled with examples of men and women adapting **natural resources** for their own uses. Egyptians of the eighteenth dynasty (1700–1500 B.C.), for example, knew how to use cobalt compounds to glaze pottery and glass. They had also developed techniques for making and using a variety of dyes.

Over the next 3,000 years, humans expanded and improved their abilities to manipulate natural chemicals. Then, in the 1850s, a remarkable breakthrough occurred. A discovery by young British scientist William Henry Perkin led to the birth of the synthetic chemicals industry.

Perkin's great discovery came about almost by accident, an occurrence that was to become common in the synthetics industry. As an 18-year-old student at England's Royal College of Chemistry, Perkin was looking for an artificial compound that could be used as a quinine substitute. Quinine, the only drug available for the treatment of **malaria**, was itself in short supply.

Following his teacher's lead, Perkin carried out a number of experiments with compounds extracted from **coal** tar, the black, sticky **sludge** obtained when coal is heated in insufficient air. Eventually, he produced a black powder which, when dissolved in alcohol, created a beautiful purple liquid. Struck by the colorful solution, Perkin tried dyeing clothes with it.

His efforts were eventually successful. He went on to mass produce the synthetic dye—mauve, as it was named—and to create an entirely new industry. The years that followed are sometimes referred to as The Mauve Decade because of the many new synthetic products inspired by Perkin's achievement. Some of the great chemists of that era have been memorialized in the names of the products they developed or the companies they established: Adolf von Baeyer (Bayer aspirin), Leo Baekeland (Baekelite plastic), Eleuthère Irénée du Pont (DuPont Chemical), George Eastman (Eastman 910 adhesive and the Eastman Kodak Company), and Charles Goodyear (Goodyear **Rubber**).

Chemists soon learned that from the gooey, ugly byproducts of coal tar, a whole host of new products could be made. Among these products were dyes, medicines, fibers, flavorings, **plastics**, explosives, and **detergents**. They found that the other fossil fuels—petroleum and natural gas—could also produce synthetic chemicals.

Today, synthetic chemicals permeate our lives. They are at least as much a part of the **environment**, if not more, than are natural chemicals. They make life healthier, safer, and more enjoyable. People concerned about the abundance of "chemicals" in our environment should remember that everyone benefits from anti-cancer drugs, pain-killing anesthetics, long-lasting fibers, vivid dyes, sturdy synthetic rubber tires, and dozens of other products. The world would be a much poorer place without them.

Unfortunately, the production, use, and disposal of synthetic chemicals can create problems because they may be persistent and/or hazardous. Persistent means that a substance remains in the environment for a long time: dozens, hundreds, or thousands of years in many cases. Natural products such as wood and paper degrade naturally as they are consumed by **microorganisms**. Synthetic chemicals, however, have not been around long enough for such microorganisms to evolve.

This leads to the familiar problem of **solid waste** disposal. Plastics used for bottles, wrappings, containers, and hundreds of other purposes do not decay. As a result, landfills become crowded and communities need new places to dump their trash.

Persistence is even more of a problem if a chemical is hazardous. Some chemicals are a problem, for example, because they are flammable. More commonly, however, a hazardous chemical will adversely affect the health of a plant or animal. It may be (1) toxic, (2) carcinogenic, (3) teratogenic, or (4) mutagenic.

Toxic chemicals cause people, animals, or plants to become ill, develop a disease, or die. DDT, **chlordane**, heptachlor, and aldrin are familiar, toxic pesticides. Carcinogens cause **cancer**; teratogens produce **birth defects**. Mutagens, perhaps the most sinister of all, inflict genetic damage.

Determining these effects can often be very difficult. Scientists can usually determine if a chemical will harm or kill a person. But how does one determine if a chemical causes cancer twenty years after exposure, is responsible for birth defects, or produces genetic disorders? After all, any number of factors may have been responsible for each of these health problems.

As a result, labeling any specific chemical as carcinogenic, teratogenic, or mutagenic can be difficult. Still, envi-

ronmental scientists have prepared a list of synthetic chemicals that they believe fall into these categories. Among them are **vinyl chloride**, trichloroethylene, **tetrachloroethylene**, the nitrosamines, and chlordane and heptachlor.

Another class of chemicals are hazardous because they may contribute to the **greenhouse effect** and **ozone layer depletion**. The single most important chemical in determining the earth's annual average temperature is a naturally-occurring compound, **carbon dioxide**. Its increased production is believed to be responsible for a gradual increase in the planet's annual average temperature.

But synthetic compounds may also play a role in global warming. **Chlorofluorocarbons** (CFCs) are widely used in industry because of their many desirable properties, one of which is their chemical **stability**. This very property means, however, that when released into the **atmosphere**, they remain there for many years. Since they capture heat radiated from the earth in much the way **carbon** dioxide does, they are probably important contributors to global warming.

These same chemicals, highly unreactive on earth, decompose easily in the upper atmosphere. When they do so, they react with the **ozone** in the **stratosphere**, converting it to ordinary oxygen. This may have serious consequences, since stratospheric ozone shields the earth from harmful **ultraviolet radiation**.

There are two ways to deal with potentially hazardous chemicals in the environment. One is to take political or legal action to reduce the production, limit the use, and/or control the disposal of such products. A treaty negotiated and signed in Montreal by more than forty nations in 1987, for example, calls for a gradual ban on CFC production. If the treaty is honored, these chemicals will eventually be phased out of use.

A second approach is to solve the problem scientifically. Synthetic chemicals are a product of scientific research, and science can often solve the problems these chemicals produce. For example, scientists are exploring the possibility of replacing CFCs with related compounds called fluorocarbons (FCs) or hydrochloroflurocarbons (HCFCs). Both are commercially appealing, but they have fewer harmful effects on the environment.

Chemosynthesis

Chemosynthesis is a metabolic pathway used by some bacteria to synthesize new organic compounds such as carbohydrates by using energy derived from the oxidation of inorganic molecules—hydrogen sulfide (H_2S) or ammonia (NH_3). Chemosynthesis can occur in environments such as the deep ocean around **hydrothermal vents**, where sunlight does not penetrate, but where **chemicals** like **hydrogen** sulfide are available. Chemosynthesis is also a critical part of the **nitrogen cycle**, where bacteria that live in the **soil**, or in special plant structures called heterocysts, utilize ammonia for energy and produce **nitrates and nitrites** which can subsequently be used as nutrients for plants. Some bacteria can also utilize hydrogen gas (H_2) and **carbon dioxide** (CO_2) in a chemosynthetic pathway that results in the production of new organic compounds and **methane** (CH_4).

[*Marie H. Bundy*]

Chernobyl nuclear power station

On April 26, 1986, at precisely 1:24 A.M., the Chernobyl **nuclear power** plant exploded, releasing large amounts of **radioactivity** into the **environment**. The power station is located 9 mi (14.5 km) northwest of the town of Chernobyl, with a population of 12,500, and less than 2 mi (3.2 km) from the town of Pripyat, which contains 45,000 inhabitants. The explosion and its aftermath, including the manner in which the accident was handled, have raised questions about the safety and future of nuclear power.

The Chernobyl accident resulted from several factors: flaws in the engineering design, which were compensated by a strict set of procedures; failure of the plant management to enforce these procedures; and finally the decision of the engineers to conduct a risky experiment. They wanted to test whether the plant's turbine generator—from its rotating inertia—could provide enough power to the reactor in case of a power shutdown. This experiment required disconnecting the reactor's emergency core cooling pump and other safety devices.

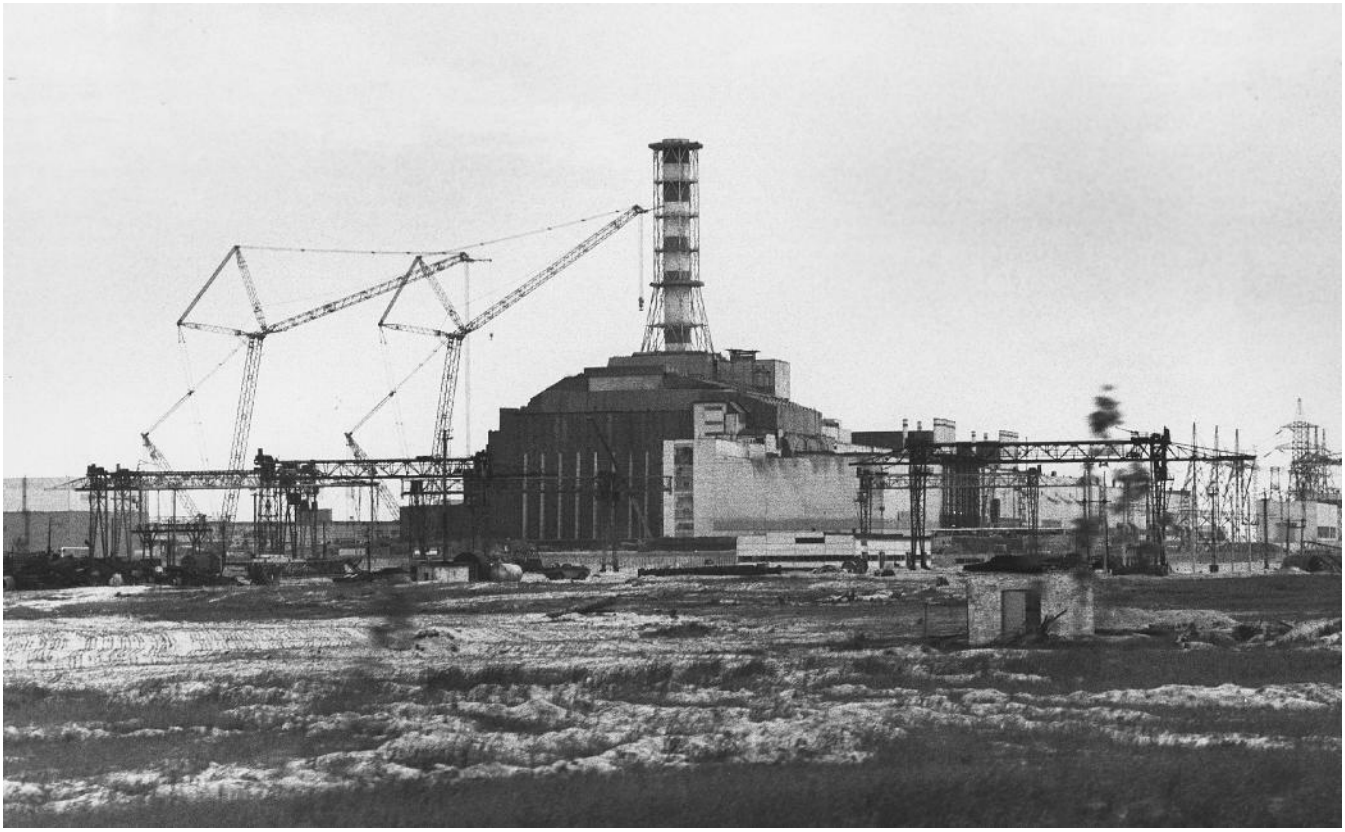
The series of critical events, as described by Richard Mould in *Chernobyl, The Real Story*, are as follows: At 1:00 A.M. on April 25, power reduction was started in preparation for the experiment. At 1:40 A.M. the reactors's emergency core cooling system was turned off. At 11:10 P.M. power was further reduced, resulting in a nearly unmanageable situation. At 1:00 A.M. on April 26, power was increased in an attempt to stabilize the reactor; however, cooling pumps were operating well beyond their rated capacity, causing a reduction in steam generation and a fall in stream pressure. By 1:19 A.M., the water in the cooling circuit had approached

the boiling point. At 1:23 A.M., the operators tried to control the reaction by manually pushing control rods into the core; however, the rods did not descend their full length into the reactor since destruction of the graphite core was already occurring. In 4.5 seconds, the power level rose two thousandfold. At 1:24 A.M., there was an explosion when the hot reactor fuel elements, lacking enough liquid for cooling, decomposed the water into **hydrogen** and oxygen. The generated pressures blew off the 1,000-ton concrete roof of the reactor, and burning graphite, molten **uranium**, and radioactive ashes spilled out to the **atmosphere**.

The explosion that occurred was not a nuclear explosion such as would occur with an atomic bomb but its effects were just as devastating. In order to put the expulsion of radioactive material from the Chernobyl reactor into perspective, almost 50 tons of fuel went into the atmosphere plus an additional 70 tons of fuel, and 700 tons of radioactive reactor graphite settled in the vicinity of the damaged unit. Some 50 tons of nuclear fuel and 800 tons of reactor graphite remained in the reactor vault, with the graphite burning up completely in the next several days after the accident. The amount of radioactive material that went into the atmosphere was equivalent to 10 Hiroshima bombs.

Officials at first denied that there had been a serious accident at the power plant. The government in Moscow was led to believe for several hours after the explosion and fire at Chernobyl that the reactor core was still intact. This delayed the evacuation for a critical period during which local citizens were exposed to high radiation levels. The evacuation of Chernobyl and local villages was spread out over eight days. A total of 135,000 persons were evacuated from the area, with the major evacuation at Pripyat starting at 2:00 P.M., the day after the explosion. Tests showed that air, water, and **soil** around the plant had significant contamination. Children, in particular, were a matter of concern and were evacuated to the southern Ukraine, the Crimea, and the Black Sea coast.

At the time of the accident, and for several days thereafter, the winds carried the **radioactive waste** to the north. The radioactive cloud split into two lobes, one spreading west and then north through Poland, Germany, Belgium, and Holland, and the other through Sweden and Finland. By the first of May, the wind direction changed and the radioactive fallout—at a diminished rate—went south over the Balkans and then west through Italy. Large areas of Europe were affected, and many farmers destroyed their crops for fear of contamination. Forests have been cleared and large amounts of earth were removed in order to clean up radioactivity. Plastic film has been laid in some areas in an effort to contain radioactive dust.



Officially 31 persons were reported to have been killed at the reactor site by a combination of the explosion and **radiation exposure**; another 174 were exposed to high doses of radiation which resulted in **radiation sickness** and long-term illnesses. The maximum permissible dose of radiation for a nuclear power operator is 5 roentgens per year and for the rest of the population, 0.5 roentgens per year. At the Chernobyl plant, the levels of radiation ranged from 1,000 to 20,000 roentgens per hour. One British report estimates that worldwide, the number of persons afflicted with **cancer** which can be attributed to the Chernobyl accident will be about 2,300. Others argued that the number will be much higher. In Minsk, the rate of **leukemia** has more than doubled from 41 per million in 1985 to 93 per million in 1990.

Many heroic deeds were reported during this emergency. Fire fighters exposed themselves to deadly radiation while trying to stop the inferno. Every one eventually died from radiation exposure. Construction workers volunteered to entomb the reactor ruins with a massive concrete sarcophagus. Bus drivers risked further exposure by making repeated trips into contaminated areas in order to evacuate villagers. Over 600,000 people were involved in the decontamination and clean up of Chernobyl. The health effects on them from their exposure are not completely known. The Chernobyl accident focused international attention on the risks associated with operating a nuclear reactor for the generation of power. Public apprehension has forced some governments to review their own safety procedures and to compare the operation of their nuclear reactors with Chernobyl's. In a review of the Chernobyl accident by the Atomic Energy Authority of the United Kingdom, an effort was made to contrast the design of the Chernobyl reactor and management procedures with those in practice in the United States and the United Kingdom.

Three design drawbacks were noted of the Chernobyl nuclear power plant:

- The reactor was intrinsically unstable below 20% power and never should have been operated in that mode. (U.S. and UK reactors do not have this design flaw).
- The shut-down operating system was inadequate and contributed to the accident rather than terminating it. (U.S. and UK control systems differ significantly).
- There were no controls to prevent the staff from operating the reactor in the unstable region or preventing the disabling of existing safeguards.

In addition, the Chernobyl management had no effective watchdog agency to inspect procedures and order closure of the facility. Also in years prior to the accident there was a lack of information given the public of prior nuclear accidents, typical of the press censorship and news management occurring in the period before *glasnost*. The operators were not adequately trained nor were they themselves fully aware of prior nuclear power accidents or near accidents

Chernobyl Nuclear Power Station. Lighter areas of the buidling are part of the original structure, while darker areas are the steel and concrete "sarcophagus" that was added to contain radioactivity leaking from the faulty reactor. (Corbis-Bettmann. Reproduced by permission.)

which would have made them more sensitive to the dangers of a runaway reactor system.

Unfortunately in the former Soviet block nations there are several nuclear reactors that are potentially as hazardous as Chernobyl but which must continue operation to maintain power requirements; however, the operational procedures are under constant review to avoid another accident. Clearly the Western world will have to assist the former Soviet block to bring reactor operating equipment and standards up to a much higher level of safety to avoid a similar and possibly more disastrous accident.

Chesapeake Bay

The Chesapeake Bay is the largest **estuary** (186 mi [300 km] long) in the United States. The Bay was formed 1500 years ago by the retreat of glaciers and the subsequent sea level rise that inundated the lower Susquehanna River valley. The Bay has a **drainage** basin of 64,076 square miles (166,000 sq km) covering six states and running through Pennsylvania, Maryland, the District of Columbia, and Virginia before entering the Atlantic Ocean. While 150 rivers enter the Bay, a mere eight account for 90% of the freshwater input, with the Susquehanna alone contributing nearly half. Chesapeake Bay is a complex system, composed of numerous habitats and environmental gradients.

Chesapeake Bay's abundant **natural resources** attracted native Americans, first settling on its shores. The first European record of the Bay was in 1572 and the area

surrounding Chesapeake Bay was rapidly colonized by Europeans. In many ways, the United States grew up around Chesapeake Bay. The colonists harvested the Bay's resources and used its waterways for **transportation**. Today 10 million people live in the Chesapeake Bay's drainage basin, and many of their activities affect the environmental quality of the Bay as did the activities of their ancestors.

The rivers emptying into the Bay were also used by the colonists to dispose of raw sewage. By the middle 1800s some of the rivers feeding the Bay were polluted: the Potomac was recorded as emitting a lingering stench. The first sewer was constructed in Washington, DC, and it pumped untreated waste into the Bay. It was recognized in 1893 that the diseases suffered by humans consuming shellfish from the Bay were directly related to the **discharge** of raw sewage into the Bay. Despite this recognition, efforts in 1897 by the mayor of Baltimore to oppose the construction of a sewage system that discharged sewage into the Bay in favor of a "land **filtration** technique" failed. Ultimately, a secondary treatment system discharging into the Bay was constructed. In the mid-1970s, a $27 million government-funded study of the Bay's condition concluded that the deteriorating quality of the Chesapeake Bay was a consequence of human impacts. But it was not until the early 1980s that an **Environmental Protection Agency** (EPA) report on the Chesapeake focused interest on saving the Bay, and $500 million was spent on cleanup and construction of **sewage treatment** plants.

While the Chesapeake Bay is used primarily as a transportation corridor, its natural resources rank a close second in importance to humans. The most commercially important fisheries in the Bay are the native American oyster (*Crassostrea virginica*), blue crab (*Callinectes sapidus*), American shad (*Alosa sapidissima*), and striped bass (*Marone saxatilis*). Fisherman first began to notice a decline in fish populations in the 1940s and 1950s, and since then abundances have declined even further. Since the turn of the century, the oyster catch has declined 70%, shad 85%, and striped bass 90%. In the late 1970s, the EPA began to study the declining oyster and striped bass populations and concluded that their decline was due to a combination of over-harvesting and **pollution**.

Work by the EPA and other federal and state agencies has identified six areas of environmental concern for the Bay: (1) excess **nutrient** input from both sewage treatment plants discharging into the Bay and **runoff** from agricultural land; (2) low oxygen levels as a result of increased **biochemical oxygen demand**, which increases dramatically with **loading** of organic material; (3) loss of **submerged aquatic vegetation** due to an increase in turbidity; (4) presence of chemical **toxins**; (5) loss to development of **wetlands** surrounding the Bay that serve as nurseries for juvenile fish and shellfish and as buffers for runoff of nutrients and toxic **chemicals**; and (6) increasing acidity of water (measured by **pH**) in streams that feed the Bay. These streams are also nursery areas for larval fish that may be adversely affected by decreasing pH.

The increasing growth of phytoplankton—free-floating single- celled plants—in the Bay is generally considered to be a significant contributor to the decline in environmental quality of the Chesapeake Bay. The number of algal blooms has increased dramatically since the 1950s and is attributed to the high levels of the plant nutrients **nitrogen** and **phosphorus** that are discharged into the Bay. In the 1980s and 1990s, it was estimated that discharge from sewage treatment plants and agricultural runoff accounted for 65% of the nitrogen and 22% of the phosphorus found in the Bay. **Acid rain**, formed from discharges from industrial plants in Canada and the northeast United States, contributed 25% of the nitrogen found in the Bay. Excess nutrients encourage **phytoplankton** growth, and as the large number of phytoplankton die and settle to the bottom, their **decomposition** robs the water of oxygen needed by fish and other aquatic organisms. When oxygen levels fall too low, these organisms die or flee from the regions of low oxygen. Decomposition of dead organic matter further reduces the concentration of oxygen. During the late twentieth and early twenty-first centuries, Finfish and shellfish kills became increasingly common in the Bay.

Phytoplankton blooms and the increase in suspended sediments resulting from shoreline development and poor agricultural practices have increased turbidity and led to a decline in submerged aquatic vegetation (SAV) such as **eelgrass**. SAV is extremely important in the prevention of **erosion** of bottom **sediment** and as **critical habitat** for nursery grounds of commercially important fish and shellfish.

Chemicals introduced into the Bay from several sites may have contributed to the decline in the Bay's fish and bird populations. For example, in 1975, the **pesticide Kepone** was leaked or dumped into the James River, **poisoning** fish and shellfish. Harvests of some **species** are still restricted in the area of this spill. **Chlorine** biocides used in **wastewater** treatment plants and **power plants**, which discharge into the Bay, are known human carcinogens and can be toxic to aquatic organisms. **Polycyclic aromatic hydrocarbons** (PAH) have caused dermal lesions in fish populations in the Elizabeth River. PAHs also affect shellfish populations. In the 1990s, public concern focused on **tributyl tin** (TBT) that was used in anti-fouling paint on recreational and commercial boats. TBTs belong to a family of chemicals known as organotins, which are toxic to shellfish and crustaceans. The diversity of chemical pollutants found in the Bay is exemplified by the results of research that identified 100

inorganic and organic contaminants in striped bass caught in the Bay. As of 2002, research efforts were underway to determine the extent of the damage from toxins to natural resources.

Work by private and governmental agencies has started to reverse the declining environmental quality of the Chesapeake Bay. In 1983 Maryland, Virginia, Pennsylvania, the District of Columbia, the Chesapeake Bay Commission, and the EPA signed the Chesapeake Bay Agreement, which outlined procedures to correct many of the Bay's ecological problems, particularly those caused by nutrient enrichment. In 1987 the agreement was significantly expanded and required that the signatories adopt a strategy that would result in at least a 40% reduction in nitrogen and phosphorus entering the Bay by the year 2000. Since 1985, increasing compliance with discharge permits, prohibition of the sale of phosphate-based **detergents**, and the upgrading of wastewater plants has resulted in a 2% reduction in the discharge of nitrogen and a 39% reduction of phosphorous from point sources of pollution. Controls on agriculture and urban development have resulted in approximately 7% reductions in the amount of both nitrogen and phosphorus entering the Bay from nonpoint sources. The amount of toxins entering the Bay have also been reduced. Tributyl tin has been banned for use in anti-fouling paints on non-military vessels, pesticide runoff has been reduced by using alternate strategies for **pest** control, and since 1987, toxic emissions from industrial sources have declined more than 40%. At the same time, some of the Bay's critical habitats are recovering: 22,000 more acres of SAVs are now growing than in 1984, although the total amount of 60,000 acres is still a fraction of the estimated 600,000 acres the historical SAV distribution, man-made oyster reefs are being created to expand suitable **habitat** for oysters, and rivers are being cleared of obstacles such as **dams** and spillways to provide access to spawning areas by migratory fish.

Conflict between commercial and environmental interests have encumbered some of the restoration efforts. Research on the life-history of crabs and oysters shows that limiting the size of crabs that can be sold and the numbers of oysters that can be harvested will help these fisheries rebound, but regulations to limit crab and oyster catches have met with strong **resistance** from watermen who are struggling to survive economically in a declining fishery.

The planned introduction of a non-native Asian oyster (*Crassostrea ariakensis*) by the Virginia Seafood Council, raised hopes that a new oyster fishery could be built around the harvest of this disease-resistant, fast-growing species. In May 2002, the United States **Fish and Wildlife Service** called for a moratorium on the introduction of the Asian oyster, until researchers could determine whether its introduction would endanger native species, or bring new and deadly disease organisms into Chesapeake Bay. A study by the **National Academy of Sciences** was commenced in 2001 with the goal of making information on these concerns available in summer of 2003.

As of 2002, portions of Chesapeake Bay and its tributaries were still listed as impaired waters under Section 303(d) of the **Clean Water Act**, but progress on arresting the decline of environmental quality of Chesapeake Bay and restoring some of its natural resources continued. In the Chesapeake 2000 Bay Agreement (C2K), Maryland, Pennsylvania, Virginia, and the District of Columbia, together with the Chesapeake Bay Commission and the Federal Government committed to "correct the nutrient- and sediment-related problems in the Chesapeake Bay and its tidal tributaries sufficiently to remove the Bay and the tidal portions of its tributaries from the list of impaired waters under the Clean Water Act." This consortium of stakeholders, jurisdictions, and federal agencies is evidence that citizens, government, and industry can work cooperatively. The Chesapeake Bay program is a national model for efforts to restore other degraded ecosystems.

Child survival revolution

Every year in the developing countries of the world, some 14 million children under the age of five die of common infectious diseases. Most of these children could be saved by simple, inexpensive, preventative medicine. Many public health officials argue that it is as immoral and unethical to allow children to die of easily preventable diseases as it would be to allow them to starve to death or to be murdered. In 1986, the United Nations announced a worldwide campaign to prevent unnecessary child deaths. Called the "child survival revolution," this campaign is based on four principles, designated by the acronym GOBI.

"G" stands for growth monitoring. A healthy child is considered a growing child. Underweight children are much more susceptible to infectious diseases, retardation, and other medical problems than children who are better nourished. Regular growth monitoring is the first step in health maintenance.

"O" stands for oral rehydration therapy (ORT). About one-third of all deaths under five years of age are caused by diarrheal diseases. A simple solution of salts, glucose, or rice powder and boiled water given orally is almost miraculously effective in preventing death from dehydration shock in these diseases. The cost of treatment is only a few cents per child. The British medical journal *Lancet*, called ORT "the most important medical advance of the century."

"B" stands for breast-feeding. Babies who are breast-fed receive natural immunity to diseases from antibodies in their mothers' milk, but infant formula companies have been persuading mothers in many developing countries that bottle-feeding is more modern and healthful than breast-feeding. Unfortunately, these mothers usually do not have access to clean water to combine with the formula and they cannot afford enough expensive synthetic formula to nourish their babies adequately. Consequently, the **mortality** among bottle-fed babies is much higher than among breast-fed babies in developing countries.

"I" is for universal immunization against the six largest, preventable, **communicable diseases** of the world: measles, tetanus, tuberculosis, polio, diphtheria, and whooping cough. In 1975, less than 10% of the developing world's children had been immunized. By 1990, this number had risen to over 50%. Although the goal of full immunization for all children has not yet been reached, many lives are being saved every year. In some countries, yellow fever, typhoid, meningitis, **cholera**, and other diseases also urgently need attention.

Burkina Faso provides an excellent example of how a successful immunization campaign can be carried out. Although this West African nation is one of the poorest in the world (annual gross national product per capita of only $140), and its roads, health care clinics, communication, and educational facilities are either nonexistent or woefully inadequate, a highly successful "vaccination commando" operation was undertaken in 1985. In a single three-week period, one million children were immunized against three major diseases (measles, yellow fever, and meningitis) with only a single injection. This represents 60% of all children under age 14 in the country. The cost was less than $1 per child.

In addition to being an issue of humanity and compassion, reducing child mortality may be one of the best ways to stabilize world **population growth**. There has never been a reduction in birth rates that was not preceded by a reduction in infant mortality. When parents are confident that their children will survive, they tend to have only the number of children they actually want, rather than "compensating" for likely deaths by extra births. In Bangladesh, where ORT was discovered, a children's health campaign in the slums of Dacca has reduced infant mortality rates 21% since 1983. In that same period, the use of birth control increased 45% and birth rates decreased 21%.

Sri Lanka, China, Costa Rica, Thailand, and the Republic of Korea have reduced child deaths to a level comparable to those in many highly developed countries. This child survival revolution has been followed by low birth rates and stabilizing populations. The United Nations Children's Fund estimates that if all developing countries had been able to achieve similar birth and death rates, there would have been nine million fewer child deaths in 1987, and nearly 22 million fewer births. *See also* Demographic transition

Chimpanzees

Common chimpanzees (*Pan troglodytes*) are widespread in the forested parts of West, Central, and East Africa. Pygmy chimpanzees, or bonobos (*P. paniscus*), are restricted to the swampy lowland forests of the Zaire basin. Despite their names, common chimpanzees are no longer common, and pygmy chimpanzees are no smaller than the other **species**.

Chimpanzees are partly arboreal and partly ground-dwelling. They feed in fruit trees by day, nest in other trees at night, and can move rapidly through treetops. On the ground chimpanzees usually walk on all fours (knuckle walking), since their arms are longer than their legs. Their hands have fully opposable thumbs and, although lacking a **precision** grip, can manipulate objects dexterously. Chimpanzees make and use a variety of tools: they shape and strip "fishing sticks" from twigs to poke into termite mounds, and they chew the ends of shoots to fashion fly whisks. They also throw sticks and stones as offensive weapons and hunt and kill young monkeys.

These apes live in small nomadic groups of three to six animals (common chimpanzee) or six to 15 animals (pygmy chimpanzee) which make up a larger community (30–80 individuals) that occupies a territory. Adult males cooperate in defending their territory against predators. Chimpanzee

A chimpanzee (*Pan troglodytes*). (Photograph by Nigel J. Dennis. Photo Researchers Inc. Reproduced by permission.)(Photograph by Nigel J. Dennis. Photo Researchers Inc. Reproduced by permission.)

society consists of fairly promiscuous mixed-sex groups. Female common chimpanzees are sexually receptive for only a brief period in mid-month (estrous), while female pygmy chimpanzees are sexually receptive for most of the month. Ovulating females capable of fertilization have swollen pink hind quarters and copulate with most of the males in the group. Female chimpanzees give birth to a single infant after a gestation period of about eight months.

Jane Goodall has studied common chimpanzees for almost 30 years in the Gombe Stream **National Park** of Tanzania. She found that chimpanzee personalities are as variable as those of humans, that chimpanzees form alliances, have friendships, have personal dislikes, and run feuds. Chimpanzees also have a cultural tradition, that is, they pass learned behavior and skills from generation to generation. Chimpanzees have been taught complex sign language (the chimpanzee larynx won't allow speech) through which abstract ideas have been conveyed. These studies show that chimpanzees can develop a large vocabulary and that they can manipulate this vocabulary to frame new thoughts.

Humans share 98.4% of their genes with chimpanzees, so only 1.6% of human DNA is responsible for all the differences between the two species. The DNA of gorillas differs 2.3% from chimpanzees, which means that the closest relatives of chimpanzees are humans, not gorillas. Further studies of these close relatives would undoubtedly help to better understand the origins of human social behavior and human **evolution**. Despite this special status, both species of chimpanzees are threatened by the destruction of their forest **habitat** by **hunting** and by capture for research.

Chipko Andolan movement

India has a long history of non-violent, passive **resistance** in social movements rooted in its Hindu concept of *ahimsa*, or "no harm." During the British occupation of India in the early twentieth century, Indian leader Mohandas K. Gandhi began to employ a method of resistance against the British that he called *satyagraha* (meaning "force of truth"). Synthesized from his knowledge of **Henry David Thoreau**, Leo Tolstoy, Christianity and Hinduism, Gandhi's concept of satyagraha involves the absolute refusal to cooperate with a

perceived wrong and the use of nonviolent tactics in combination with complete honesty to confront, and ultimately convert, evil.

During the occupation, the rights of peasants to gather products, including forest materials, was severely curtailed. New land ownership systems imposed by the British transformed what had been communal village resources into the private property of newly created landlords. Furthermore, policies that encouraged commercial exploitation of forests were put into place. Trees were felled on a large scale to build ships for the British Royal Navy or to provide ties for the expanding railway network in India, severely depleting forest resources on which traditional cultures had long depended.

In response to British rule with its forest destruction and impoverishment of native people, a series of non-violent movements utilizing satyagraha spread throughout India. The British and local aristocracy suppressed these protests brutally, massacring unarmed villagers by the thousands, and jailing Gandhi a number of times, but Gandhi and his allies remained steadfast in their resistance. The British, forced to comprehend the horror of their actions and unable to scapegoat the nonviolent Indians, at last withdrew from India.

After India gained independence, two of Gandhi's disciples, Mira Behn and Sarala Behn, moved to the foothills of the Himalayas to establish *ashramas* (spiritual retreats) dedicated to raising women's status and rights. Their project was dedicated to four major goals: 1) organizing local women, 2) campaigning against alcohol consumption, 3) fighting for forest protection, and 4) setting up small, local, forest-based industries.

During the 1970s, commercial loggers began large-scale tree felling in the Garhwal region in the state of Uttar Pradesh in northern India. Landslides and floods resulted from stripping the forest cover from the hills. The firewood on which local people depended was destroyed, threatening the way of life of the traditional forest culture.

In April, 1973, village women from the Gopeshwar region who had been educated and empowered by the principles of non-violence devised by the Behns began to confront loggers directly, wrapping their arms around trees to protect them. The outpouring of support sparked by their actions was dubbed the *Chipko Andolan* movement (literally, "movement to hug trees"). This crusade to save the forests eventually prevented **logging** on 4,633 mi^2 (12,000 km^2) of sensitive watersheds in the Alakanada basin. Today, the Chipko Andolan movement has grown to more than four thousand groups working to save India's forests. Their slogan is: "What do the forests bear? **Soil**, water, and pure air."

The successes of this movement, both in empowering local women and in saving the forests on which they depend, are inspiring models for grassroots green movements around the world.

Chlordane

Chlordane and a closely related compound, heptachlor, belong to a group of chlorine-based pesticides known as cyclodienes. They were among the first major **chemicals** to attract national attention and controversy, mainly because of their devastating effects on **wildlife** and domestic animals. By the 1970s, they had become two of the most popular pesticides for home and agricultural uses (especially for termite control), despite links between these chemicals and the **poisoning** of birds and other wildlife, pets and farm animals, as well as links to **leukemia** and other cancers in humans.

In 1975, environmentalists finally persuaded **Environmental Protection Agency** (EPA) to issue an immediate temporary ban on most uses of chlordane and heptachlor based on an "imminent hazard of **cancer** in man." In 1978, when the EPA agreed to phase out most remaining uses of chlordane and heptachlor, the agency stated that "virtually every person in the United States has residues...in his body tissues." Chlordane has now been banned, at least temporarily, for sale or use in the U.S. But potentially dangerous levels of the chemical are still found occasionally in foodstuffs, homes, and the **environment**.

Chlorinated hydrocarbons

Chlorinated **hydrocarbons** are compounds made of **carbon**, **hydrogen**, and **chlorine** atoms. These compounds can be aliphatic, meaning they do not contain **benzene**, or aromatic, meaning they do. The chlorine functional group gives these compounds a certain character; for instance, the

aromatic organochlorine compounds are resistant to microbial degradation; the aliphatic chlorinated solvents have certain anesthetic properties (e.g., chloroform); some are known for their antiseptic properties (e.g., hexachloraphene). The presence of chlorine imparts toxicity to many organochlorine compounds (e.g., chlorinated pesticides).

Chlorinated hydrocarbons have many uses, including chlorinated solvents, organochlorine pesticides, and industrial compounds. Common chlorinated solvents are dichloromethane (methylene chloride), chloroform, carbon tetrachloride, trichloroethane, trichloroethylene, tetrachloroethane, **tetrachloroethylene**. These compounds are used in drycleaning solvents, degreasing agents for machinery and vehicles, paint thinners and removers, laboratory solvents, and in manufacturing processes, such as coffee decaffeination. These solvents are hazardous to human health and exposures are regulated in the workplace. Some are being phased out for their toxicity to humans and the **environment**, as molecules have the potential to react with and destroy stratospheric **ozone**.

The organochlorine pesticides include several subgroups, including the cyclodiene insecticides (e.g., **chlordane**, heptachlor, dieldrin), the DDT family of compounds and its analogs, and the hexachlorocyclohexanes (often incorrectly referred to as BHCs, or benzene hexachlorides). These insecticides were developed and marketed extensively after World War II, but due to their toxicity, persistence, widespread environmental contamination, and adverse ecological impacts, most were banned or restricted for use in the United States in the 1970s and 80s. These insecticides generally have low water solubilities, a high affinity for organic matter, readily bioaccumulate in plants and animals, particularly aquatic organisms, and have long environmental half-lives compared to the currently-used insecticides.

There are many chlorinated industrial products and reagent materials. Examples include **vinyl chloride**, which is used to make PVC (**polyvinyl chloride**) **plastics**; chlorinated benzenes, including hexachlorobenzene; PCB (polychlorinated biphenyl), used extensively in electrical transformers and capacitors; chlorinated phenols, including **pentachlorophenol** (PCP); chlorinated naphthalenes; and chlorinated diphenylethers. They represent a diversity of applications, and are valued for their low reactivity and high insulating properties.

There are also chlorinated byproducts of environmental concern, particularly the polychlorinated dibenzo-p-dioxins (PCDDs) and the polychlorinated dibenzofurans (PCDFs). These families of compounds are products of incomplete **combustion** of organochlorine-containing materials, and are primarily found in the **fly ash** of **municipal solid waste** incinerators. The most toxic component of PCDDs, 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD), was a trace contaminant in the production of the **herbicide 2,4,5-T** and is found in trace amounts in 2,4,5-trichlorophenol and technical grade pentachlorophenol. PCDDs and PCDFs can also be formed in the chlorine bleaching process of **pulp and paper mills**, and have been found in their **effluent** and in trace amounts in some paper products.

Chlorination

Chlorination refers to the application of **chlorine** for the purposes of oxidation. The forms of chlorine used for chlorination include: chlorine gas, hypochlorous **acid** (HOCl), hypochlorite **ion** (OCl), and chloramines or combined chlorine (Mono-, di-, and tri-chloramines). The first three forms of chlorine are known as free chlorine.

Chlorine (Cl) has three valences under normal environmental conditions, -1, 0 and +1. Environmental scientists often refer only to the chlorine forms having 0 and +1 valences as chlorine; they refer to the -1 form as chloride. Chlorine with a valence of 0 (Cl_2) and chlorine with a valence of +1 (HOCl) both have the ability to oxidize materials, whereas chlorine at a -1 valence, chloride, is already at its lowest oxidation state and has no oxidizing power.

The functions of chlorination are to disinfect water or **wastewater**, decolorize waters or fabrics, sanitize and clean surfaces, remove iron and manganese, and reduce odors. The fundamental principle of each application is that due to its oxidizing potential, chlorine is able to effect many types of chemical reactions. Chlorine can cause alterations in DNA, cell-membrane porosity, **enzyme** configurations, and other biochemicals; the oxidative process can also lead to the death of a cell or **virus**. Chemical bonds, such as those in certain dyes, can be oxidized, causing a change in the color of a substance. Textile companies sometimes use chlorine to decolorize fabrics or process waters. In some cases, odors can be reduced or eliminated through oxidation. However, the odor of certain compounds, such as some phenolics, is aggravated through a reaction with chlorine. Certain soluble metals can be made insoluble through oxidation by chlorine

(soluble Fe^{2+} is oxidized to insoluble Fe^{3+}), making the metal easier to remove through **sedimentation** or **filtration**.

Chlorine is commercially available in three forms; it can also be generated on-site. For treating small quantities of water, calcium hypochlorite ($Ca(OCl)_2$), commonly referred to as high test hypochlorite (HTH) because one mole of HTH provides two OCl^- ions, is sometimes used. For large applications, chlorine gas (Cl_2) is the most wide used source of chlorine. It reacts readily with water to form various chlorine **species** and is generally the least expensive source. There are, however, risks associated with the handling and transport of chlorine gas, and these have convinced some to use sodium hypochlorite (NaOCl) instead. Sodium hypochlorite is more expensive than chlorine gas, but less expensive than calcium hypochlorite. Some utilities and industries have generated chlorine on-site for many years, using electrolysis to oxidize chloride ions to chlorine. The process is practical in remote areas where brine, a source of chloride ions, is readily available.

Chlorine has been used in the United States since the early 1900s for disinfection. It is still commonly used to disinfect wastewater and drinking water, but the rules guiding its use are gradually changing. Until recently, chlorine was added to wastewater effluents from treatment plants without great concern over its effects on the **environment**. The environmental impact was thought to be insignificant since chlorine was being used in such low concentrations. However, evidence has accumulated showing serious environmental consequences from the **discharge** of even low levels of various forms of chlorine and chlorine compounds, and many plants now dechlorinate their wastewater after allowing the chlorine to react with the wastewater for 30–60 minutes.

The use of chlorine to disinfect drinking water is undergoing a similar review. Since the 1970s, it has been suspected that chlorine and some by-products of chlorination are carcinogenic. Papers published in 1974 indicated that halogenated methanes are formed during chlorination. During the mid-1970s the **Environmental Protection Agency** (EPA) conducted two surveys of the **drinking-water supply** in the United States, the National Organics Reconnaissance Survey and the National Organics Monitoring Survey, to determine the extent to which **trihalomethanes** (THMs) (chloroform, bromodichloromethane, dibromochloromethane, bromoform) and other halogenated organic compounds were present. The studies indicated that drinking water is the primary route by which humans are exposed to THMs and that THMs are the most commonly detected synthetic organic **chemicals** in United States' drinking water.

Chloroform was the THM found in the highest concentrations during the surveys. The risks associated with drinking water containing high levels of chloroform are not clear. It is known that 0.2 qt (200 ml) of chloroform is usually fatal to humans, but the highest concentrations in the drinking water surveyed fell far below (311 ug/l) this lethal dose. The potential carcinogenic effects of chloroform are more difficult to evaluate. It does not cause *Salmonella typhimurium* in the **Ames test** to mutate, but it does cause mutations in yeast and has been found to cause tumors in rats and mice. However, the ability of chloroform to cause **cancer** in humans is still questionable, and the EPA has classified it and other THMs as probable human carcinogens. Based on these data, the maximum contaminant level for THMs in drinking water is now 100 ug/l. This is an enforceable standard and requires the monitoring and reporting of THM concentrations in drinking water.

There are several ways to test for chlorine, but among the more common methods are iodometric, DPD (N,N-Diethyl-p-phenylenediamine) and amperometric. DPD and amperometric methods are generally used in the water and wastewater treatment industry. DPD is a dye which is oxidized by the presence of chlorine, creating a reddish color. The intensity of the color can then be measured and related to chlorine level; the DPD solution can be titrated with a reducing agent (ferrous ammonium sulfate) until the reddish color dissipates. In the amperometric titration method, an oxidant sets up a current in a solution which is measured by the amperometric titrator. A reducing agent (phenylarsine oxide) is then added slowly until no current can be measured by the titrator. The amount of titrant added is commonly related to the amount of chlorine present.

To minimize the problem of chlorinated by-products, many cities in the United States, including Denver, Portland, St. Louis, Boston, Indianapolis, Minneapolis, and Dallas, use chloramination rather than simple chlorination. Chlorine is still required for chloramination, but ammonia is added before or at the same time to form chloramines. Chloramines do not react with organic precursors to form halogenated by-products including THMs. The problem in using chloramines is that they are not as effective as the free chlorine forms at killing pathogens.

Questions still remain about whether the levels of chlorine currently used are dangerous to human health. The level of chlorine in most water supplies is approximately 1 mg/l, and some scientists believe that the chlorinated by-products formed are not hazardous to humans at these levels. There are some risks, nevertheless, and perhaps the most important question is whether these outweigh the benefits of using chlorine. The final issue concerns the short-term and long-term effects of discharging chlorine into the environment. Dechlorination would be yet another treatment step, requiring the commitment of additional resources. At the present time, the general consensus is that chlorine is more beneficial than harmful. However, it is important to

note that a great deal of research is now underway to explore the benefits of using alternative disinfectants such as **ozone**, chlorine dioxide, and ultraviolet light. Each alternative poses some problems of its own, so despite the current availability of a great deal of research data, the selection of an alternative is difficult.

Chlorine

Chlorine is an element of atomic number 17 and atomic mass of 35.45 atomic mass units. It belongs to Group 17 of the periodic table and is thus a halogen. Halogens are a highly reactive group of elements that, in addition to chlorine, include fluorine, iodine, **bromine** and another element that does not occur in **nature**, astatine, but is produced by bombarding bismuth with alpha particles. Halogens are extremely reactive because they have an unpaired electron in their outermost electron shell. Thus so highly reactive, chlorine is usually not found in a pure form in nature, but is rather typically bound to other elements such as sodium, calcium, or potassium. In its pure form, chlorine exists as a diatomic molecule, meaning a molecule containing two of the same atoms. This form of chlorine is a yellow-green gas at room temperature. Chlorine gas is more dense than air, condenses to form a liquid at -29°F(-34°C), and freezes into a solid at -153°F(-103°C). Because of its reactivity, desirable properties, and abundance, chlorine is an exceptionally useful element. Since it readily combines with other elements and molecules, chlorine is a main component and vital reactant in the manufacture of thousands of useful products. In addition, almost all municipal **water treatment** systems in the United States depend on chlorine **chemicals** to provide clean and safe drinking water. It is estimated that chlorine is used in the production of 85% of all pharmaceuticals, and in 96% of all crop protection chemicals (pesticides and herbicides). Also, chlorine chemicals are powerful bleaching agents used in paper processing and inexpensive but highly effective disinfectants.

Chlorine also has an important impact on the economy. The chlorine industry provides almost 2 million jobs having a combined yearly payroll of over $52 billion. In the United States, 212 industries are direct users of chlorine or related products. The Chlorine Chemistry Council reports that nearly 40% of U.S. jobs and income are directly or indirectly dependent on chlorine. The chlorine-dependent industries are mostly found in Texas, Michigan, and New Jersey. The **automobile** industry relies heavily on chlorine because cars contain many components that use chlorine in their manufacture. Three chlorine products, PVC, pickled steel, and paint create more than 345,000 jobs in the United States. Polyvinylchloride (or PVC) is a chlorinated hydrocarbon polymer that is used to make dashboards, air bags, wire covers, and sidings. Chlorine is also used in the manufacture of car exterior paints. Automobile coatings typically use titanium dioxide which requires chlorine for synthesis. In addition, chlorine is used in the production of pickled steel for automobile frames and undercarriages. The pickling process provides an impurity-free steel surface for rust **resistance** treatment and painting. Hydrochloric **acid**, a chlorine chemical, is a main component in pickling steel. Roughly 25% of the hydrochloric acid produced in the United States is used in steel pickling for the auto industry. Overall, the auto industry consumes 3.1% of all chlorine produced in the form of hydrochloric acid, 30% of all chlorine produced in the form of PVC, and 4.1% of all chlorine produced involved in the manufacture of titanium dioxide for paints.

Industrially, chlorine is also used in massive quantities for **sanitation** purposes. An important advancement in public health has been the widespread **chlorination** of drinking water. Chlorine-based water purifying chemicals were first introduced in 1908. Chlorine water purification has practically eradicated diseases that were once devastating, such as **cholera** and dysentery. In 1992, the Public Health Advisory Board was created to guide the chlorine industry in issues pertaining to drinking water safety. Because it is so highly reactive, chlorine is one of the most effective germicides available. Chlorine chemicals kill bacteria, algae, **fungi**, and protozoans and inactivate viruses. Simple household bleach, sodium hypochlorite, can even inactivate and sterilize equipment from such deadly viruses as the **Ebola virus**. Chlorine is also used to sanitize pools and spas. Chlorine disinfectants are used to prevent institutional disease transmission in food preparation, day care centers, nursing homes, and hospitals.

Chlorine is a vital chemical in the pharmaceutical and medical industries. Approximately 85% of all drugs either contain chlorine or are manufactured using chlorine. The chemical addition of chlorine to a drug molecule can enhance its **absorption** and delay its elimination from the body, increasing the duration of its action. Also, chlorine can be used to create soluble forms of drugs that dissolve easily into solutions. When hydrochloric acid is reacted with poorly soluble drugs that are weak bases, the result is a chloride salt that is more soluble in water. Greater solubility enhances absorption and allows some drugs to be incorporated into syrups or elixirs. This is very useful since many people prefer oral liquid drug intake. Soluble drugs also have the advantage that they can be inhjected. Finally, about 25% of all medical

equipment is made from **chlorinated hydrocarbons**, vinyl or PVC.

Chlorinated **hydrocarbons** are specific hydrocarbon molecules that also have atoms of the element chlorine chemically bonded to them. The number of **carbon** atoms and how they are arranged in three-dimensions determines the chemical and physical properties of these compounds. Because there is a wide variety of possible chlorinated hydrocarbons, this class of useful chemicals has a wide range of applications that are of great economic and practical importance. Chlorinated hydrocarbons include products such as the synthetic rubbers used in car tires and tennis shoes. They are also used in packaging **plastics**, and a variety of products such as fluid pipes, furniture, home siding, credit cards, fences, and toys. Chlorinated hydrocarbons also can be used as precursors in the production of non-stick coatings such as Teflon. Chlorine is also used in the manufacture of solvents such as carbon tetrachloride and trichloroethylene used in **dry cleaning**.

In addition to their use in the manufacture of polymers, rubbers, plastics, solvents, and cleaners, chlorinated hydrocarbons also are powerful pesticides. They rank among the most potent and environmentally persistent insecticides, and when combined with fluorine, they yield the refrigerants called **chlorofluorocarbons**, or CFCs. Because of their wide array of uses, chlorinated hydrocarbons are among the most important industrial organic compounds. Perhaps the best known chlorinated hydrocarbon insecticide is *Dichloro-DiphenylTrichloroethane, or DDT*. DDT was first used as an insecticide in 1939. After its effectiveness and relative safety to humans was established, the use of DDT burgeoned around the world in the war against disease-carrying and agricultural insect pests. However, the very success of DDT in the fight against insect-transmitted diseases (especially **malaria**) subsequently led to its massive overuse. Widespread excessive use led to the emergence of DDT-resistant insects. Additionally, evidence started to show that toxic levels of DDT could accumulate in the fatty tissues of mammals, including humans. Because of such harmful effects, the use of DDT has now been banned in many countries despite its effectiveness. Another important issue with chlorinated hydrocarbons is their environmental persistence. Many, such as DDT, refrigerants, and solvents are not easily broken-down in the environent. Also, because other, less persistent, insecticide alternatives have been developed, the use of chlorinated insecticides has been drastically reduced.

Other toxic chemicals resistant to degradation also contain chlorine such as chlorinated and **polychlorinated biphenyls** (PCBs) and polyaromatic hydrocarbons (PAHs). These substances are known environmental pollutants, with PAHs found for example in diesel exhaust emissions and PCBs in industrial effluents, contaminating rivers as well as the Oceans. They have been shown to accumulate in **whales** and a variety of other marine mammals.

Another environmentally important chlorine compound class are the chemicals known as *ChloroFluoroCarbons*, or CFCs. Chlorofluorocarbons are single carbon atoms chemically bound to both chlorine and fluorine. The compounds trichlorofluoromethane (Freon-11) and dichlorodifluoromethane (Freon-12) are widely used CFCs. They are odorless, nonflammable, very stable compounds that are used as refrigerants in commercial refrigerators and air conditioners. CFCs are also used as **aerosol propellants**. Because CFCs are detrimental to the **ozone** layer, the portion of the **atmosphere** that blocks out the harmful wavelengths of ultraviolet light associated with skin **cancer**, they are being phased out as propellants and refrigerants. An ozone hole detected above **Antarctica** has been attributed by scientists to the release of CFCs into the atmosphere.

The **Environmental Protection Agency** (EPA) is concerned with toxic and persistent chlorine chemicals that are the byproducts of industrial activity. Two such byproducts are dioxins and **furans**, produced when organic (carbon-containing) compounds are heated to high temperatures in the presence of chlorine. Together, dioxins and furans represent a group of over two hundred chemicals. Some dioxins are extremely toxic and are a significant cause for concern to environmental agencies. **Dioxin** compounds are highly persistent in the **environment**. The most toxic dioxin is 2,3,7,8-tetrachlorodibenzo-p-dioxin or TCDD. Dioxins are also by-products of industrial processes involving chlorine such as waste **incineration**, chemical and **pesticide** manufacturing and pulp and paper bleaching. Dioxin is a known **carcinogen** and was the principal toxic component of **Agent Orange**. The EPA reports that incinerators are the largest source of dioxins and furans released into the environment in the United States. Other industrial sources of these toxic compounds include smelters, cement kilns, and fossil fuel burning **power plants**. Because of new standards for incineration, the levels of dioxins and furans have been steadily declining.

Chlorine monoxide

One of two oxides of **chlorine**, either Cl_2O or ClO. When used in **environmental science**, it usually refers to the latter. Chlorine monoxide (ClO) is formed in the **atmosphere** when free chlorine atoms react with **ozone**. In the reaction, ozone is converted to normal, diatomic oxygen (O_2). This process appears to be a major factor in the destruction of ozone in the **stratosphere** observed by scientists in recent years. The most important sources of chlorine by which this reaction is initiated appear to be **chlorofluorocarbons** and other synthetic chlorine compounds released by human activities.

Chlorofluorocarbons

The chlorofluorocarbons (CFCs) are a family of organic compounds containing **carbon**, **hydrogen** (usually), and either **chlorine** or fluorine, or both. The members of this family can be produced by replacing one or more hydrogen atoms in **hydrocarbons** with a chlorine or fluorine atom. In the simplest possible case, treating **methane** (CH_4) with chlorine yields chloromethane, CH_3Cl. Treating this product with fluorine causes the replacement of a second hydrogen atom with a fluorine atom, producing chlorofluoromethane, CH_2ClF.

This process can be continued until all hydrogen atoms have been replaced by chlorine and/or fluorine atoms. By using larger hydrocarbons, an even greater variety of CFCs can be produced. The compound known as CFC-113, for example, is made from ethane (C_2H_6) and has the formula $C_2F_3Cl_3$.

Over the last three decades, the CFCs have become widely popular for a number of commercial applications. These applications fall into four general categories: refrigerants, cleaning fluids, **propellants**, and blowing agents. As refrigerants, CFCs have largely replaced more harmful gases such as ammonia and **sulfur dioxide** in refrigerators, freezers, and air conditioning systems. Their primary application as cleaning fluids has been in the computer manufacturing business where they are used to clean circuit boards. CFCs are used as propellants in hair sprays, deodorants, spray paints, and other types of sprays. As blowing agents, CFCs are used in the manufacture of fast-food take-out boxes and similar containers. By the early 1990s, CFCs had become so popular that their production was a multi-billion dollar business worldwide.

For many years, little concern was expressed about the environmental hazards of CFCs. The very qualities that made them desirable for commercial applications—their **stability**, for example—appeared to make them environmentally benign.

However, by the mid-1970s, the error in that view became apparent. Scientists began to find that CFCs in the **stratosphere** decomposed by sunlight. One product of that **decomposition**, atomic chlorine, reacts with **ozone** (O_3) to form ordinary oxygen (O_2). The apparently harmless CFCs turned out, instead, to be a major factor in the loss of ozone from the stratosphere.

By the time this discovery was made, levels of CFCs in the stratosphere were escalating rapidly. The concentration of these compounds climbed from 0.8 part per billion in 1950 and 1.0 part per billion in 1970 to 3.5 **parts per billion** in 1987.

A turning point in the CFC story came in the mid-1980s when scientists found that a large hole in the ozone layer was opening up over the Antarctic each year. This discovery spurred world leaders to act on the problem of CFC production. In 1987, about 40 nations met in Montreal to draft a treaty that will reduce the production of CFCs worldwide.

This action is encouraging, but it hardly solves the CFC problem. These compounds remain in the **atmosphere** for long periods of time (about 77 years for CFC-11 and 139 years for CFC-12), so they will continue to pose a threat to the ozone layer for many decades to come.

Cholera

Cholera is one of the most severe and contagious diseases transmitted by water. It is marked by severe diarrhea, resulting in fluid loss and dehydration, sometimes followed by shock and death. If not treated, **mortality** occurs in over 60% of cases. The Latin American cholera epidemic claimed 4,002 lives in 1991, and resulted in 391,742 reported cases that year, mostly in Peru and Ecuador. Cholera is caused by the bacillus *Vibrio cholerae*, a member of the family Vibrionaceae, which are described as Gram negative, non-sporulating rods that are slightly curved, motile, and have a fermentative **metabolism**.

The natural **habitat** of *V. cholerae* is human feces, but some studies have indicated that natural waters may also be a habitat of the organism. Fecal contamination of water is the most common means by which *V. cholerae* is spread, however, food, insects, soiled clothing, or person-to-person contact may also transmit sufficient numbers of the **pathogen** to cause cholera.

The ability of *V. cholerae* to survive in water is dependent upon the temperature and water type. *V. cholerae* reportedly survive longer at low temperatures, and in seawater, sterilized water, and **nutrient** rich waters. Also, the particular strain of *V. cholerae* affects the survival of the organism in water, since some strains or types are hardier than others. Most methods to isolate *V. cholerae* from water include concentration of the sample, by **filtration**, exposure to high **pH** and selective media. Identification of pathogenic strains of *V. cholerae* is dependent upon agglutination tests. Final confirmation of the strain or type must be done in a specialized laboratory.

Persons infected with *V. cholerae* produce 10^7 to 10^9 organisms per milliliter in the stool at the height of the disease, but the number of excreted organisms drops off quickly as the disease progresses. Asymptomatic carriers of *V. cholerae* excrete 10^2 to 10^5 organisms per gram of feces. The mild form of the illness lasts for five to seven days. Hydration therapy is the treatment of choice for cholera. It is suggested that antibiotics not be used, following the emergence of multiple antibiotic resistant strains in many areas. Vaccines exist to prevent cholera, however, they do not prevent the acquisition of the bacteria in the gastrointestinal tract, do not diminish symptoms in persons already infected, and are effective for well less than a year. Proper **water treatment** should eliminate *V. cholerae* from drinking water, however, the most effective control of this pathogen is dependent upon good sanitary practices.

Cholinesterase inhibitor

Insecticides kill their target insect **species** in a variety of ways. Two of the most commonly used classes of insecticide are the organophosphates (nerve gases) and the carbamates. These compounds act quickly (in a matter of hours), are lethal at low doses (**parts per billion**), degrade rapidly (in hours to days) and leave few toxic residues in the **environment**. Organophosphates kill insects by inducing loss of control of the peripheral nervous system, leading to uncontrollable spasms followed by paralysis and, ultimately, death. This is often accomplished by a biochemical process called cholinesterase inhibition.

Most animals' nervous systems are composed of individual nerve cells called neurons. Between any two adjacent neurons there is always a gap, called the synaptic cleft; the neurons do not actually touch each other. When an animal senses something—for example, pain—the sensation is transmitted chemically from one neuron to another until the impulse reaches the brain or central nervous system. The first neuron (pre-synaptic neuron) releases a substance, known as a transmitter, into the synaptic cleft. One of the most common chemical transmitters is called acetylcholine. Acetylcholine then diffuses across the gap and binds with receptor sites on the second neuron (post-synaptic neuron). Reactions within the target neuron triggered by occupied receptors result in further transmission of the signal. As soon as the impulse has been transmitted, the acetylcholine in the gap is immediately destroyed by an **enzyme** called cholinesterase; the destruction of the acetylcholine is an absolutely essential part of the nervous process. If the acetylcholine is not destroyed, it continues to stimulate indefinitely the transmission of impulses from one neuron to the next, leading to loss of all control over the peripheral nervous system. When control is lost, the nervous system is first overstimu-

lated and then paralyzed until the animal dies. Thus, **organophosphate** insecticides bind to the cholinesterase enzyme, preventing the cholinesterase from destroying the acetylcholine and inducing the death of the insect.

Some trade names for organophosphate insecticides are malathion and parathion. Carbamates include aminocarb and carbaryl. The carbamates produce the same effect of cholinesterase inhibition as the organophosphates, but the chemical reaction of the carbamates is more easily reversible. The potency or power of these compounds is usually measured in terms of the quantity of the **pesticide** (or inhibitor) that will produce a 50% loss of cholinesterase activity. Since acetylcholine transmission of nervous impulses is common to most vertebrates as well as insects, there is a great potential for harm to non-target species from the use of cholinesterase-inhibiting insecticides. Therefore the use of these insecticides is highly regulated and controlled. Access to treated areas and contact with the compounds is prohibited until the time period necessary for the breakdown of the compounds to non-toxic end products has elapsed.

Chromatography

Chromatography is the process of separating mixtures of **chemicals** into individual components as a means of identification or purification. It derives from the Greek words *chroma,* meaning color, and *graphy,* meaning writing. The word was coined in 1906 by the Russian chemist Mikhail Tsvett who used a column to separate plant pigments. Currently chromatography is applied to many types of separations far beyond those of just color separations. Common chromatographic applications include gas-liquid chromatography (GC), liquid-solid chromatography (LC), thin layer chromatography (TLC), **ion exchange** chromatography, and gel permeation chromatography (GPC). All of these methods are invaluable in analytical **environmental chemistry**, particularly GC, LC, and GPC.

The basic principle of chromatography is that different compounds have different retentions when passed through a given medium. In a chromatographic system, one has a mobile phase and a stationary phase. The mixture to be separated is introduced in the mobile phase and passed through the stationary phase. The compounds are selectively retained by the stationary phase and move at different rates which allows the compounds to be separated.

In gas chromatography, the mobile phase is a gas and the stationary phase is a liquid fixed to a solid support. Liquid samples are first vaporized in the injection port and carried to the chromatographic column by an inert gas which serves as the mobile phase. The column contains the liquid stationary phase, and the compounds are separated based on their different vapor pressures and their different affinities for the stationary phase. Thus different types of separations can be optimized by choosing different stationary phases, and by altering the temperature of the column. As the compounds elute from the end of the column, they are detected by one of a number of methods that have specificity for different chemical classes.

Liquid chromatography consists of a liquid mobile phase and a solid stationary phase. There are two general types of liquid chromatography: column chromatography and high pressure liquid chromatography (HPLC). In column chromatography, the mixture is eluted through the column containing stationary packing material by passing successive volumes of solvents or solvent mixtures through the column. Separations result as a function of both chemical-solvent interactions as well as chemical-stationary phase interactions. Often this technique is used in a preparative manner to remove interferences from environmental sample extracts. HPLC refers to specific instruments designed to perform liquid chromatography under very high pressures to obtain a much greater degree of resolution. The column outflow is passed through a detector and can be collected for further processing if desired. Detection is typically by ultraviolet light or fluorescence.

A variation of column chromatography is gel permeation chromatography (GPC), which separates chemicals based on size exclusion. The column is packed with porous spheres, which allow certain size chemicals to penetrate the spheres and excludes larger sizes. As the sample mixture traverses the column, larger molecules move more quickly and elute first while smaller molecules require longer elution times. An example of this application in environmental analyses is the removal of lipids (large molecules) from fish tissue extracts being analyzed for pesticides (small molecules).

Chronic effects

Chronic effects occur over a long period of time. The length of time termed "long" is dependent upon the life cycle of the organism being tested. For some aquatic **species** a chronic effect might be seen over the course of a month. For animals such as rats and dogs, chronic would refer to a period of several weeks to years.

Chronic effects can be either caused by chronic or acute exposures. Acute exposure to some metals and many carcinogens can result in chronic effects. With certain toxicants, such as cyanide, it is difficult, if not impossible, to cause a chronic effect. However, at a higher dosage, cyanide readily causes **acute effects**. Examples of chronic effects include pulmonary tuberculosis and, in many cases, **lead poisoning**. In each disease the effects are long-term and cause damage to tissues; acute effects generally result in little tissue reaction. Thus, acute and chronic effects are frequently unrelated, and yet it is often necessary to predict chronic toxicity based on acute data. Acute data are more plentiful and easier to obtain. To illustrate the possible differences between acute and chronic effects, consider the examples of halogenated solvents, **arsenic**, and lead.

In halogenated solvents, acute exposure can cause excitability and dizziness, while chronic exposure will result in liver damage. Chronic effects of arsenic poisoning are in blood formation and liver and nerve damage. Acute poisoning affects the gastro-intestinal tract. Lead also effects blood formation in chronic exposure, and damages the gastro-intestinal tract in acute exposure. Other chronic effects of exposure to lead include changes in the nervous system and muscles. In some situations, given the proper combination of dose level and frequency, those exposed will experience both acute and chronic effects.

There are **chemicals** that are essential and beneficial for the functions and structure of the body. The chronic effect is therefore better health, although people generally do not refer to chronic effects as being positive. However, vitamin D, fluoride, and sodium chloride are just a few examples of agents that are essential and/or beneficial when administered at the proper dosage. Too much of any of the three or too little, however, could cause acute and/or chronic toxic effects.

In **aquatic toxicology**, chronic toxicity tests are used to estimate the effect and no-effect concentrations of a chemical that is continuously applied over the reproductive life cycle of an organism; for example, the time needed for growth, development, sexual maturity, and reproduction. The range in chemical concentrations used in the chronic tests is determined from acute tests. Criterion for effects might include the number and percent of embryos that develop and hatch, the survival and growth of larvae and juveniles, etc.

The maximum acceptable toxicant concentration (MATC) is defined through chronic testing. The MATC is a hypothetical concentration between the highest concentration of chemical that caused no observed effect (NOEC) and the lowest observed effect concentration (LOEC). Therefore,

$$\text{LOEC} > \text{MATC} > \text{NOEC}$$

Furthermore, the MATC has been used to relate chronic toxicity to acute toxicity through an application factor (AF). AF is defined as follows:

$$\text{AF} = \frac{\text{MATC}}{\text{LD}_{50}}$$

The AF for one aquatic species might then be used to predict the chronic toxicity for another species, given the acute toxicity data for that species.

The major limitations of chronic toxicity testing are the availability of suitable test species and the length of time needed for a test. In animal testing, mice, rats, rabbits, guinea pigs, and/or dogs are generally used; mice and rats being the most common. With respect to aquatic studies, the most commonly used vertebrates are the fathead (fresh water) and sheepshead (saltwater) minnows. The most commonly used invertebrates are freshwater water fleas (*Daphnia*) and the saltwater mysid shrimp (*Mysidopsis*). *See also* Aquatic chemistry; Detoxification; Dose response; Heavy metals and heavy metal poisoning; LD_{50}; Plant pathology; Toxic substance

Cigarette smoke

Cigarette **smoke** contains more than 4,000 identified compounds. Many are known irritants and carcinogens. Since the first Surgeon General's Report on smoking and health in 1964, evidence linking the use of **tobacco** to illness, injury, and death has continued to mount. Many thousands of studies have documented the adverse health consequences of any type of tobacco, including cigarettes, cigars, and smokeless tobacco.

Specific airborne contaminants from cigarette smoke include respirable particles, nicotine, **polycyclic aromatic hydrocarbons**, **arsenic**, DDT, formaldehyde, **hydrogen**

cyanide, **methane**, **carbon monoxide**, acrolein, and **nitrogen** dioxide. Each one of these compounds impacts some part of the body. Irritating gases like ammonia, hydrogen sulfide and formaldehyde affect the eyes, nose and throat. Others, like nicotine, impact the central nervous system. **Carbon** monoxide reduces the oxygen-carrying capacity of the blood, starving the body of energy. Carcinogenic agents come into prolonged contact with vital organs and with the delicate linings of the nose, mouth, throat, lungs and airways.

Cigarette smoke is one of the six major sources of indoor **air pollution**, along with **combustion** by-products, **microorganisms** and allergens, formaldehyde and other organic compounds, **asbestos** fibers, and **radon** and its airborne decay products. The carbon monoxide concentration in cigarette smoke is more than 600 times the level considered safe in industrial plants, and a smoker's blood typically has 4 to 15 times more carbon monoxide in it than that of a nonsmoker. Airborne particle concentrations in a home with several heavy smokers can exceed **ambient air** quality standards.

Sidestream, or second-hand, smoke actually has higher concentrations of some **toxins** than the mainstream smoke the smoker inhales. Second-hand smoke carries more than 30 known carcinogens. According to a study by the **Centers for Disease Control and Prevention** (CDC) released in 1996, nearly nine out of 10 nonsmoking Americans are exposed to environmental tobacco smoke as measured by the levels of cotinine in their blood. The presence of cotinine, a chemical the body metabolizes from nicotine, is documentation of exposure to cigarette smoke. On the basis of health hazards of second-hand smoke, the **Environmental Protection Agency** has classified second-hand smoke as a Group A **carcinogen**, known to cause **cancer** in humans.

Cigarettes probably represent the single greatest source of **radiation exposure** to smokers in the United States today. Two naturally occurring radioactive materials, lead-210 and polonium-210, are present in tobacco. Both of these long-lived decay products of radon are deposited and retained on the large, sticky leaves of tobacco plants. When the tobacco is made into cigarettes and the smoker lights up, the radon decay products are volatilized and enter the lungs. The resulting dose to small segments of the bronchial epithelium of the lungs of about 50 million smokers in the United States is about 160 mSv per year. (One Sv = 100 rem of radiation.) The dose to the whole body is about 13 mSv, more than 10 times the long-term dose rate limit for members of the public.

The U. S. Department of Health and Human Services reported in 1996 that more than 430,000 Americans die each year from smoking. One in every five deaths in the United States is smoking related, the largest preventable cause of illness and premature death in the United States About 10 million people in the United States have died from causes attributed to smoking, including heart disease, **emphysema**, and other respiratory disease, since the first Surgeon General's report on smoking and health in 1964. Death is caused primarily by heart disease, lung cancer, heart disease, and chronic obstructive lung diseases such as emphysema or chronic **bronchitis**. In addition, the use of tobacco has been linked to cancers of the larynx, mouth and esophagus, and as a contributory factor in the development of cancers of the bladder, kidney, pancreas, and cervix. Cigarette smoke aggravates **asthma**, triggers allergies, and causes changes in bodily tissues that can leave smokers and nonsmokers prone to illness, especially heart disease.

About 180,000 Americans will die prematurely of coronary heart disease every year due to smoking. The risk of a stroke or heart attack is greatly increased by nicotine, which impacts the platelets which enable the blood to clot. Nicotine causes the surface of the platelets to become stickier, thereby increasing the platelets' ability to aggregate. Thus, a blood clot or thrombus forms more easily. A thrombus in an artery of the heart results in a heart attack; in an artery of the brain it results in a stroke.

Epidemiological studies reveal a direct correlation between the extent of maternal smoking and various illnesses in children. Also, studies show significantly lower heights and weights in six to 11-year olds whose mothers smoke. A pregnant woman who smokes faces increased risks of miscarriage, premature birth, stillbirth, infants with low birth weight, and infants with physical and mental impairments. Cigarette smoking also impairs fertility in women and men, contributes to earlier menopause, and increases a woman's risk of osteoporosis.

Cigarette smoke contains **benzene** which, when combined with the radioactive toxins, can cause **leukemia**. Although smoking does not cause the disease, smoking may boost a person's risk of getting leukemia by 30%.

A long-time smoker increases his risk of lung cancer by 1,000 times. In 1986, according to the CDC, about 117,000 people died of lung cancer directly attributed to cigarette smoke. More than 3,000 people each year develop lung cancer from second-hand smoke. Between 1960 and 1990, deaths from lung cancer among women have increased by more than 400%—exceeding breast cancer deaths.

The addiction to nicotine in cigarette smoke, a chemical and behavioral addiction as powerful as that of heroin, is well documented. The immediate effect of smoking a cigarette can range from tachycardia (an abnormally fast heartbeat) to arrhythmia (an irregular heartbeat). Deep inhalations of smoke lower the pressure in a smoker's chest and pulmonary blood vessels, which increases the amount of blood flow to the heart. This increased blood flow is experienced as a relaxed feeling. Seconds later, nicotine enters the

liver and causes that organ to release sugar, which leads to a "sugar high." The pancreas then releases insulin to return the blood sugar level to normal, but it makes the smoker irritable and hungry, stimulating a desire to smoke and recover the relaxed, high feeling.

Nicotine also stimulates the nervous system to release adrenaline, which speeds up the heart and respiratory rates, making the smoker feel more tense. Lighting the next cigarette perpetuates the cycle. The greater the number of behaviors linked to the habit, the stronger the habit is and the more difficult to break. Quitting involves combating the physical need and the psychological need, and complete physical withdrawal can take up to two weeks.

From an economic point of view, the Department of Health and Human Services estimates that smoking costs the United States $50 billion in health expenses. That figure is most likely conservative because the medical costs attributable to burn care from smoking-related fires, perinatal care for low birth weight infants of mothers who smoke, and treatment of disease caused by second-hand smoke were not included in the calculation.

Citizen science

Becoming a Citizen Scientist, according to the Cornell University Laboratory of Ornithology, can be as simple as glancing periodically at your backyard bird feeder, or as complicated as getting out in the field, collecting data about the relationship between an environments characteristics and the success of bird-nesting in that milieu. Put simply, citizen science is the practice of involving individual citizens, through their voluntary efforts, in the work of **environmental science**. Such voluntary assistance encompasses a wide variety of environmentally-related issues and projects, including the counting of various **species** of bird, monitoring rainfall amounts, or observing and surveying the habits of threatened species of **wildlife**. The goal of all environmental science, whether performed by private citizens or environmental scientists, is the same: to provide for the health of the planet, its **natural resources**, and all living beings.

John Fein, an internationally-renowned science educator, and associate professor at Griffith University (Brisbane, Queensland, **Australia**), described this participatory process as one that can "bridge the gap between science and the community and between scientific research and policy, decision-making and planning." "Bridging these gaps," he went on to note, "involves a process of social learning through sound environmental research, full public participation, the adoption of **adaptive management** practices and the development of the democratic values, skills and institutions for an active civil society."

In the United States, citizen science began in the 1800s, and became more formalized in 1886, when the **National Audubon Society** was created. According to its preamble, the societys aim was to: promote the **conservation** of wildlife and the natural environment, and educate man regarding his relationship with, and place within, the natural environment as an ecological system. Public awareness of environmental concerns increased with the first Earth Day in 1970. The significance of **Earth Day** has served as a reminder to the world community that it is not only the scientists who are responsible for the health of the **environment**. The general public, each individual, has been given the challenge to take measures large or small that might add up to an enormous improvement in the ecological scheme of life.

Today there are so many citizen science projects initiated by various environmental organizations that it would be impossible to list all of them. However, some of the better known include:

- The Christmas Bird Count, the oldest citizen science project in existence, according to the National Audubon Society. It occurs on a daily basis across the United States between December 14th and January 5th each year. Until the recent era of the home computer, it had been the practice for groups to go on birding outings, "into nature" in order to do the count.
- The Great Backyard Bird Count, occurring for three days commencing on Valentine Day involves volunteers counting the birds visiting in their backyards or in nearby parks, and entering the data into their computers. This count is then analyzed and becomes available information to the bird counters" through tables, maps, and in other forms. The director of the Audubon Society in 2002, Frank Gill, worked in coordinated effort with Dr. John W. Fitzpatrick,

director of the Cornell Lab of Ornithology, in order to calculate the results.

- Project Feeder Watch, a winter-long survey of birds that visit feeders in backyards, **nature** centers, community areas, and other locales that takes place November through March.
- The Birdhouse Network—involving the installation of bird houses with volunteers monitoring bird activity throughout the breeding season, collecting data on location, **habitat** characteristics, nestings and the number of eggs produced.
- Project Pigeon Watch, counting the number of each different color, recording the colors of courting birds, and helping scientists determine the mystery of why there are so many different colors of pigeons.
- House Finch Disease Survey— the monitoring of backyard feeders, reporting presence or absence of House Finch eye disease.
- Birds in Forested Landscapes— study sites established in forests of varying sizes with volunteers counting the birds during at least two visits (using recordings of vocalizations), and searching for markers that breeding was successful, recording landscape characteristics of the site;
- Golden-winged Warbler Project— the study to survey and conduct point counts at known and potential breeding sites of this bird, using both professionals and volunteers;
- Citizen Science in the Schoolyard— projects in elementary and middle schools that educate children in various aspects of bird-watching and counting;
- BirdSource— an interactive online database operated in conjunction with the Audubon Society collecting information from numerous projects.
- Adirondack Cooperative Loon Program, an ongoing project with volunteers through the Natural History Museum of the Adirondacks, with observation of the common loon as well as the annual count that occurs every July.
- The Mid-Atlantic Integrated Assessment (MAIA). A research, monitoring, and assessment initiative under the auspices of the **Environmental Protection Agency**, in order to provide high-quality scientific information on the condition of natural resources of the Mid-Atlantic region of the east coast, including the Delaware and Chesapeake Bays, Albemarle-Pamlico Sound, and the Delmarva Coastal Bays, utilizing professional researchers and volunteers.
- Smithsonian Neighborhood Nest-watch. Utilizing backyard bird counters during breeding season to assist the Smithsonian Environmental Research Center in gathering scientific data on various birds.
- Citizen Collaborative for **Watershed** Sustainability. A project conducted within the Southeast Minnesota Bluff-lands region, and coordinating with other farming regions across the state, in order to conserve the watersheds of southeastern Minnesota.
- Connecticut Department of Environmental Protection. A citizen-based project to monitor streams and rivers, determining the chemical, physical, and biological health of the water.

Citizen science projects such as these have provided information used in decision-making resulting in the purchasing of lands that host certain threatened species during breeding time and the development of bird population management guidelines. Further, data obtained from these surveys is often published in scientific and educational journals.

Citizens respond

The **"explosion"** of popularity and participation in citizen science has been a welcome development. Both the United Nations and individual national governments have become involved, sponsoring events such as the planned 2002 U.N. global summit scheduled for Johannesburg, South Africa, between August 26th and September 4th, 2002 to examine poverty, development, and the environment.

For citizens unaware of environmental issues, it appears that more information and publicity is necessary. In an article for the *Environmental News Network (ENN)* in October 2001, Erica Gies states, "As a person who cares about environmental issues, I often find myself preaching to the choir. But when I have an opportunity to converse with people who are either uninformed or inclined to disagree, it can be difficult to communicate my passion effectively without alienating them, especially if they are people I have a long history with, such as family." To attain that goal of increasing awareness, Gies suggests using art, literature and the media. There are a variety of nonfiction books and essays, poetry; art, and music featuring environmental or nature themes, as well as the films focusing on environmental issues featured each spring at an Environmental Film Festival held in Washington, D.C. But even a comic strip can give an ecological focus. Gies quotes *Dilbert* creator, Scott Adams from his book, *The Dilbert Future* irreverently noting that, *"The children are our future. And that is why, ultimately, we're screwed unless we do something about it. If you haven't noticed, the children who are our future are good looking but they aren't all that bright. As dense as they might be, they will eventually notice that adults have spent all the money, spread disease, and turned the planet into a smoky, filthy ball of death."*

David Suzuki also offered his insights into the challenges facing the environment in an article for *ENN* in June 2002. Enumerating the biggest challenges for the environment in the next century, Suzuki noted, "I'm beginning to think one of the biggest challenges is overcoming the fact that people are tired of all the depressing news about the environment." Citizen science was offering a solution for positive approaches and answers to these issues, giving the

public a reason to be hopeful and cherish their involvement in seeing things change. One such person, Robert Boyle, of Cold Spring, NY and author of the 1969 book, *The Hudson River: A Natural and Unnatural History* continued his struggle for 30 years after the publication of his book alerting people to the decay of the **Hudson River**. His book was the waterways equivalent of the *Silent Spring* (Rachel Carson's book that alerted the public to the danger of pesticides and was responsible for much of the environmental movement of the 1960s). Boyles book was instrumental in beginning the process of cleaning up not only the Hudson River, but all other polluted waterways across the United States. In 2002, Boyle continued to fight major industrial polluters and the government in courts in his effort to preserve the natural bounty of the Hudson River.

Citizens for a Better Environment

Citizens for a Better Environment (CBE) is an organization that works to reduce exposure to toxic substances in land, water, and air. Founded in 1971, CBE has 30,000 members and operates with a $1.8 million budget. The organization also maintains regional offices in Minnesota and in Wisconsin.

CBE staff and members focus on research, public information, and advocacy to reduce toxic substances. They also meet with policy-makers on state, regional, and national levels. A staff of scientists, researchers, and policy analysts evaluate specific problems brought to the attention of CBE, testify at legislative and regulatory agency hearings, and file lawsuits in state and federal courts. The organization also conducts public education programs, and provides technical assistance to local residents and organizations that attempt to halt toxic chemical exposures.

The Chicago office won a Supreme Court decision against the construction of an incinerator in a low-income neighborhood in the Chicago area and is researching the issues on volume-based **garbage** for suburban Chicago areas. In Minnesota, the staff has developed a "Good Neighbor" program of agreements between community groups, environmental activists, businesses, and industries along the Mississippi River to reduce **pollution** of the river. In Wisconsin, **transportation** issues under study include selling ride-sharing credits to meet **Clean Air Act** standards. Selling and buying of credits between and among individuals, businesses, and polluting industries has become a lucrative way for polluters to continue their practices. CBE is attempting to close the legislative loopholes that allows this practice to continue.

The Chicago office maintains a library of books, reports, and articles on environmental pollution issues. Publications include CBE's *Environmental Review*, a quarterly

journal on the public health effects of pollution; it includes updates of CBE activities and research projects.

Clay minerals

Clay minerals contribute to the physical and chemical properties of most soils and sediments. At high concentrations they cause soils to have a sticky consistency when wet. Individual particles of clay minerals are very small with diameters less than two micrometers. Because they are so finely divided, clay minerals have a very high surface area per unit weight, ranging form 5 to 800 square meters per gram. They are much more reactive than coarser materials in soils and sediments such as **silt** and sand and clay minerals account for much of the reactivity of soils and sediments with respect to **adsorption** and **ion exchange**.

Mineralogists restrict the definition of clay minerals to those aluminosilicates (minerals predominantly composed of **aluminum**, silicon, and oxygen) which in **nature** have particle sizes two micrometers or less in diameter. These minerals have platy structures made up of sheets of silica, composed of silicon and oxygen, and alumina, which is usually composed of aluminum and oxygen, but often has iron and magnesium replacing some or all of the aluminum.

Clay minerals can be classified by the stacking of these sheets. The one to one clay minerals have alternating silica and alumina sheets; these are the least reactive of the clay minerals, and kaolinite is the most common example. The two to one minerals have layers made up of an alumina sheet sandwiched between two silica sheets. These layers have structural defects that result in negative charges, and they are stacked upon each other with interlayer cations between the layers to neutralize the negative layer charges. Common two to one clays are illite and smectite.

In smectites, often called montmorillonite, the interlayer ions can undergo cation exchange. Smectites have the greatest **ion** exchange capacity of the clay minerals and are the most plastic. In illite, the layer charge is higher than for smectite, but the cation exchange capacity is lower because most of the interlayer ions are potassium ions that are trapped between the layers and are not exchangeable.

Some **iron minerals** also can be found in the clay-sized fraction of soils and sediments. These minerals have a low capacity for ion exchange but are very important in some adsorption reactions. Gibbsite, an aluminum hydroxide mineral, is also found in the clay-sized fraction of some soils and sediments. This mineral has a reactivity similar to the iron minerals.

[*Paul R. Bloom*]

Clay-hard pan

A compacted subsurface **soil** layer. Hard pans are frequently found in soils that have undergone significant amounts of **weathering**. Clay will accumulate below the surface and cause the **subsoil** to be dense, making it difficult for roots and water to penetrate. Soils with clay pans are more susceptible to water **erosion**. Clay pans can be broken by cultivation, but over time they will re-form.

Clayoquot Sound

Clayoquot (pronounced CLACK wit) Sound, located about half way up the west coast of British Columbia's Vancouver Island, is a spectacular complex of interconnecting ocean inlets, rocky islands, and narrow fjords cut into densely forested mountains. Home to black bears, cougars, **wolves**, bald eagles, marbled murrelets, five **species** of **salmon**, and lush with ferns, mosses and other water-loving plants, the area contains the largest remaining tract of **temperate rainforest** on Vancouver Island. It also contains the southernmost pristine, coastal rainforest valleys in North America. The forest is dominated by Sitka Spruce, Western Hemlock, Western Red Cedar, and Douglas Fir, many of which can grow to 300 ft (100 m) high and 15 ft (5 m) in diameter, and live over 1,500 years.

Temperate rainforests only occur in areas with a mild, humid **climate** where a cold ocean is close to mountains. They need at least 80 in (190 cm) of rain spread fairly evenly throughout the year to keep the vegetation moist and lush. These conditions occur only along the west coasts of North America, Chile, New Zealand and Tasmania. Today, over half of these magnificent forests are gone and the only remaining large tracts on earth are in southeastern Alaska, coastal British Columbia, and Chile. This thin band of coastal temperate **rain forest** contains some of the oldest and largest trees on Earth and has more **biomass** (volume of organic material) per unit area than any other **ecosystem** in the world.

Countless complex and unique ecological processes take place in ancient forests, most of which scientists don't fully understand. A typical, old growth rain forest contains trees of all ages, but many are between 250 and 1,000 years

old. A verdant collection of ferns, mosses, and **lichens** carpets the forest floor and forms thick blankets that smother fallen tree trunks and drape the branches of standing trees. Battered by centuries of wind and rain, the canopy of the old growth forest is ragged and uneven with many broken treetops and snags. A single ancient tree can provide life-sustaining **habitat** for innumerable species of insects, birds, and small mammals that burrow in its bark, nest in its branches, den in hollow cavities in its trunk, and feed on the garden of vegetation that festoons its branches. Many of these animals never descend from the forest canopy and have yet to be studied by scientists.

Dead trees also play important ecological roles in the forest. Standing snags are home to many species of insects and cavity-nesting birds. Fallen tree trunks, decaying slowly on the humid forest floor, provide nutrients and habitat to a flourishing community of **fungi**, insects, and other woodland creatures. Tree seedlings germinate and thrive on the spongy, nutrient-rich wood of fallen "nurse logs." Over 90% of the trees in the temperate rainforest grew initially on these nurse logs. Salmon connect the coastal forest to the sea. Vast schools of salmon ascending the rivers to spawn provide a key food for at least 22 animal species including bears, eagles, and Orca **whales**. When they die, the salmon fertilize streams, providing most of the nutrients that support aquatic life that will feed young salmon until they return to the ocean. Furthermore, salmon carcasses, dragged to the shore by creatures that feed on them, provide up to half the **carbon** and **nitrogen** that nourishes streamside vegetation.

With about one quarter of the world's remaining temperate rain forest, British Columbia has been the site of intense controversy over forest harvest policies and practices, and Clayoquot Sound has been the focal point for much of that debate. For more than 20 years, the area around Clayoquot was the site of confrontations and mass demonstrations both for and against **logging**. In 1993, the area witnessed the largest peaceful civil disobedience action in Canadian history. Clayoquot became an international environmental icon. Protests in support of activists there were held at Canadian Embassies throughout the world, and a boycott of Canadian timber products threatened the country's biggest industry.

Part of the basis for opposing further logging is the **scarcity** of coastal, temperate rain forest. More than 73% of Vancouver Island has either already been logged or is slated for future harvest. While about 13% of the Island's area is set aside in parks or preserves, less than 6% of the original rain forest is protected. Of the 170 watersheds (valleys) on Vancouver Island greater than 10,000 acres (about 4,000 hectares) in size, only 12 remain undeveloped, and half of those are in Clayoquot Sound.

Logging protests began in Clayoquot Sound in the early 1980s, focusing first on Meares Island, where 90% of the forest was designated for harvest. Environmentalists and First Nations people work together to stop this logging. In 1984, the Tla-o-qui-aht and Ahousaht Bands declared the island a Tribal Park, and loggers were turned away. This was the first logging blockade in Canadian history, and it attracted strong local and national support. The two largest logging companies working in Clayoquot Sound at the time were MacMillan Bloedel and the International Forest Products (Interfor). Together, in the 1980s, these two companies were cutting nearly 1 million cubic meters (32,000 large truck loads) per year from Clayoquot Sound forests.

In 1993, the British Columbia government announced a new forestry and land-use decision that aimed to compromise between environmental, economic, and social needs of the area. It would reduce the size of clearcuts, and set aside areas deemed exceptionally valuable or sensitive. A **Sierra Club** mapping project revealed, however, that 74% of the ancient temperate rain forests would be harvested under this plan, and that many of the protected areas were bog and marginal forest. Through the summer of 1993, mass protests and road blockades occurred on a daily basis at Clayoquot Sound. Altogether, more than 12,000 people traveled to this remote location that summer to protest old growth forest logging, and 856 were arrested for blockading roads into logging areas. Rather than simply paying a fine and going home, many of the protesters insisted on going to trial so they could express their love for the forest and their dismay that it was being cut down. A collection of statements made in court was published in *Clayoquot Mass Trials: Defending the Rainforest*.

As protests continued, tempers flared. Radicals on both sides of the controversy engaged in hostile and destructive acts. Property damage included several logging bridges burned, equipment vandalized, and tree spiking. On the other side, angry loggers attacked and injured several protestors. In August, more than 5,000 people from all over British Columbia attended a demonstration in the nearby town of Ucluelet to support logging. A poll conducted about this time found that 52% of British Columbians support the Clayoquot Compromise (in favor of continued logging) while 39% opposed it. Fifty seven percent of the respondents opposed the blockades, with 35% in favor and the remainder undecided. About the same time, the Nuu-Chah-Nulth Tribal Council announced that Native bands would not support any land-use decision in Clayoquot Sound that excludes logging. It said such a decision would affect the area's economic viability and further alienate the land from potential Native use.

Probably the most powerful weapon in the environmentalists arsenal was a worldwide consumer blockade of

Canadian wood products. A highly effective public relations campaign mounted in Europe, **Australia**, and the United States made logging of ancient forests at Clayoquot an international scandal. Several large firms including General Telephone Company, Scott Paper, Walmart and Home Depot announced that they would no longer buy or sell wood or wood products harvested from old-growth forests in an unsustainable manner. To counter the bad publicity, the Provincial Government reduced the harvest at Clayoquot from 959,000 cubic meters in 1988 to 0 in 1998.

In 1999 MacMillan Bloedel signed a Memorandum of Understanding with the First Nations Tribal Council and several national environmental groups. The memorandum set up a joint venture called Iisaak Forest Resources, owned 51% by the the Nuu-chah-nulth Tribal Council, and 49% by MacMillan Bloedel. Iisaak promised it would not log areas larger than 2,470 acres (1,000 hectares) in any of Clayoquot's untouched valleys, and would practice sustainable practices focused on small scale logging, **non-timber forest products** and eco-tourism rather than clearcutting of old-growth trees. However, it said, during a transition period of 50 years or so, some old-growth logging will continue until second-growth timber grows big enough to harvest.

This joint venture presents a dilemma for many environmentalists. On one hand, they want to respect indigenous land rights, and often regard native people as having greater environmental knowledge and sensitivity than those who haven't lived on the land for so long. On the other hand, if the forestry practices of the native corporation turn out to not really be sustainable, it may be difficult for environmentalists to criticize their former allies. The Friends of Clayoquot Sound, for example, refused to sign the Memorandum of Understanding because they don't support any further cutting of old growth trees for any reason.

In 2000, Clayoquot Sound was designated a United Nations Biosphere Reserve. However, this title doesn't give the rain forest any further protection. Perhaps more valuable is the establishment of the Pacific Rim **National Park** along the coast south of the town of Tofino. Nearly 125,000 acres (50,000 hectares), much of it **old-growth forest**, is included in this new national park. MacMillan Bloedel, once the largest logging company in Canada, has been bought by the U.S.-based Weyerhaeuser Corporation. Weyerhaeuser says it intends to continue collaboration with Iisaak joint venture and will honor the memorandum of understanding on management of Clayoquot Sound. Meanwhile, Interfor continues logging ancient forests, and environmentalists fear that the cumulative effect of many small cuts will be the same as if massive clearcuts had continued.

Much of the recent environmental activism in Clayoquot Sound has focused on salmon farming. Protestors claim excess food and feces from caged fish pollutes water in the Sound. Antibiotics and **chemicals** used to prevent diseases in the densely packed fish pens can harm other sea life, and escaped domesticated fish can be a threat to wild populations. Furthermore, fish farm employees often kill marine mammals and sea birds that approach open net-cage salmon pens.

It remains to be seen whether **sustainable forestry** can preserve the ancient forests or new regulations on fish farming can protect **wildlife** and **water quality**. Even in its less than pristine state, however, the Sound is a beautiful place and offers great opportunities for a variety of types of outdoor **recreation**.

Clean Air Act (1963, 1970, 1990)

The 1970 Clean Air Act and major amendments to the act in 1977 and 1990 serve as the backbone of efforts to control **air pollution** in the United States. This law established one of the most complex regulatory programs in the country. Efforts to control air **pollution** in the United States date back to 1881, when Chicago and Cincinnati passed laws to control industrial **smoke** and soot. Other municipalities followed suit and the momentum continued to build. In 1952, Oregon became the first state to adopt a significant program to control air pollution, and three years later, the federal government became involved for the first time, when the **Air Pollution Control** Act was passed. This law provided funds to assist the states in their air **pollution control** activities.

In 1963, the first Clean Air Act was passed. The act provided permanent federal aid for research, support for the

development of state pollution control agencies, and federal involvement in cross-boundary air pollution cases. An amendment to the act in 1965 directed the Department of Health, Education and Welfare (HEW) to establish federal **emission standards** for motor vehicles. (At this time, HEW administered air pollution laws. The **Environmental Protection Agency** (EPA) was not created until 1970.) This represented a significant move by the federal government from a supportive to an active role in setting air pollution policy. The 1967 Air Quality Act provided additional funding to the states, required them to establish Air Quality Control Regions, and directed HEW to obtain and make available information on the health effects of air pollutants and to identify pollution control techniques.

The Clean Air Act of 1970 marked a dramatic change in air pollution policy in the United States. Following enactment of this law, the federal government, not the states, would be the focal point for air pollution policy. This act established the framework that continues to be the foundation for air pollution control policy today. The impetus for this change was the belief that the state-based approach was not working and increased pressure from a developing environmental consciousness across the country. Public sentiment was growing so significantly that environmental issues demanded the attention of high-ranking officials. In fact, the leading policy entrepreneurs on the issue were President Richard Nixon and Senator Edmund Muskie of Maine.

The regulatory framework of The Clean Air Act featured four key components. First, National Ambient Air Quality Standards (NAAQSs) were established for six major pollutants: **carbon monoxide**, **lead** (in 1977), **nitrogen** dioxide, ground-level **ozone** (a key component of **smog**), **particulate** matter, and **sulfur dioxide**. For each of these pollutants, sometimes referred to as criteria pollutants, primary and **secondary standards** were set. The **primary standards** were designed to protect human health; the secondary standards were based on protecting crops, forests, and buildings if the primary standards were not capable of doing so. The Act stipulated that these standards must apply to the entire country and be set by the EPA, based on the best available scientific information. The costs of attaining these standards were not among the factors considered. The EPA was also directed to set standards for less common toxic air pollutants.

Second, New Source Performance Standards (NSPSs) would be set by the EPA. These standards would determine how much air pollution would be allowed by new plants in various industrial sectors. The standards were to be based on the **best available control technology** (BACT) and best available retrofit technology (BART) available for the control of pollutants at sources such as **power plants**, steel factories, and chemical plants.

Third, mobile source **emission** standards were established to control **automobile emissions**. These standards were specified in the statute (rather than left to the EPA), and schedules for meeting them were also written into the law. It was thought that such an approach was crucial to ensure success with the powerful auto industry. The pollutants regulated were **carbon** monoxide, **hydrocarbons**, and **nitrogen oxides**, with goals of reducing the first two pollutants by 90% and nitrogen oxides by 82% by 1975.

The final component of the air protection act dealt with the implementation of the new air quality standards. Each state would be encouraged to devise a state implementation plan (SIP), specifying how the state would meet the national standards. These plans had to be approved by the EPA; if a state did not have an approved SIP, the EPA would administer the Clean Air Act in that state. However, since the federal government was in charge of establishing pollution standards for new mobile and stationary sources, even the states with an SIP had limited flexibility. The main focal point for the states was the control of existing stationary sources, and if necessary, mobile sources. The states had to set limits in their SIPs that allowed them to achieve the NAAQSs by a statutorily determined deadline. One problem with this approach was the construction of tall smokestacks, which helped move pollution out of a particular **airshed** but did not reduce overall pollution levels. The states were also charged with monitoring and enforcing the Clean Air Act.

The 1977 amendments to the Clean Air Act dealt with three main issues: nonattainment, auto emissions, and the prevention of air quality deterioration in areas where the air was already relatively clean. The first two issues were resolved primarily by delaying deadlines and increasing penalties. Largely in response to a court decision in favor of environmentalists (**Sierra Club** v. Ruckelshaus, 1972), the 1977 amendments included a program for the prevention of significant deterioration (PSD) of air that was already clean. This program would prevent polluting the air up to the national levels in areas where the air was cleaner than the standards. In Class I areas, areas with near pristine air quality, no new significant air pollution would be allowed. Class I areas are airsheds over large national parks and **wilderness** areas. In Class II areas, a moderate degree of air quality deterioration would be allowed. And finally, in Class III areas, air deterioration up to the national secondary standards would be allowed. Most of the country that had air cleaner than the NAAQSs was classified as Class II. Related to the prevention of significant deterioration was a provision to protect and enhance **visibility** in national parks and wilderness areas even if the air pollution was not a threat to human health. The impetus for this section of the bill was

the growing visibility problem in parks, especially in the Southwest.

Throughout the 1980s, efforts to further amend the Clean Air Act were stymied. President Ronald Reagan was opposed to any strengthening of the Act, which he argued would hurt the economy. In Congress, the controversy over **acid rain** between members from the Midwest and the Northeast further contributed to the stalemate. Gridlock on the issue broke with the election of George Bush, who supported amendments to the Act, and the rise of Senator George Mitchell of Maine to Senate Majority Leader. Over the next two years, the issues were hammered out between environmentalists and industry and between different regions of the country. Major players in Congress were Representatives John Dingell of Michigan and Henry Waxman of California and Senators Robert Byrd of West Virginia and Mitchell.

Major amendments to the Clean Air Act were passed in the fall of 1990. These amendments addressed four major topics: (1) **acid** rain, (2) toxic air pollutants, (3) nonattainment areas, and (4) **ozone layer depletion**. To address acid rain, the amendments mandated a 10 million ton reduction in annual sulfur dioxide emissions (a 40% reduction based on the 1980 levels) and a two million ton annual reduction in nitrogen oxides to be completed in a two-phase program by the year 2010. Most of this reduction will come from old utility power plants. The law also creates marketable pollution allowances, so that a utility that reduces emissions more than required can sell those pollution rights to another source. Economists argue that, to increase efficiency, such an approach should become more widespread for all pollution control.

Due to the failure of the toxic air pollutant provisions of the 1970 Clean Air Act, new, more stringent provisions were adopted requiring regulations for all major sources of 189 varieties of toxic air pollution within ten years. Areas of the country still in nonattainment for criteria pollutants were given from three to twenty years to meet these standards. These areas were also required to impose tighter controls to meet the standards. To help these areas and other parts of the country, the Act required stiffer motor vehicle emissions standards and cleaner **gasoline**. Finally, three chemical families that contribute to the destruction of the stratospheric ozone layer (**chlorofluorocarbons** (CFCs), hydrochloroflurocarbons (HCFCs), and methyl chloroform) were to be phased out of production and use.

In 1997, the EPA issued revised national ambient air quality standards (NAAQS), setting stricter standards for ozone and particulate matter. The American Trucking Association and other state and industry groups legally challenged the new standards on the grounds that the EPA did not have the authority under the Act to make such changes. On February 27, 2001, the U.S. Supreme Court unanimously upheld the constitutionality of the Clean Air Act as interpreted by the EPA, and all remaining legal challenges to other aspects of the standards change were rejected by a Washington DC District Court ruling in early 2002.

The Clean Air Act has met with mixed success. The national average pollutant levels for the criteria pollutants have decreased. Nevertheless, many localities have not achieved these standards and are in perpetual nonattainment. Not surprisingly, major urban areas are those most frequently in nonattainment. The pollutant for which standards are most often exceeded is ozone, or smog. This is due in part to increases in nitrogen oxides (NOx), which disperse ozone. NOx emissions increased by approximately 20% between 1970 and 2000. As a result, some parts of the country have had worsening ozone levels. According to the EPA, the average ozone levels in 29 national parks increased by over 4% between 1990 and 2000.

The greatest successes of air pollution control have come with lead, which between 1981 and 2000 was reduced by 93% (largely due to the phasing-out of leaded gasoline), and particulates, which were reduced by 47% in the same period. Overall particulate emissions were down 88% since 1970. Carbon monoxide has dropped by 25% and volatile organic compounds and sulfur dioxides have declined by over 40% each between 1970 and 2000. However, air quality analysis is complex, and it is important to note that some changes may be due to shifts in the economy, changes in weather patterns, or other such variables rather than directly attributable to the Clean Air Act.

In February 2002, President Bush introduced the "Clear Skies" legislation, an initiative that, if fully adopted, would make some significant changes to the Clean Air Act. Among them would be a weakening or elimination of new source review regulations and BART rules, and a new "cap and trade" plan that would allow power plants that produced excessive toxic emissions to 'buy credits' from other plants who had levels under the standards. The Bush administration hailed the initiative as a less expensive way to accelerate air pollution clean-up and a more economy-friendly alternative to the Kyoto Protocol for greenhouse gas reductions, while environmental groups and other critics called it a roll-back of the Clean Air Act progress.

Clean coal technology

Coal is rapidly becoming the world's most popular fuel. Today in the United States, more than half of the electricity produced comes from coal-fired **power plants**. The demand for coal is expected to triple by the middle of the next century, making it more widely used than **petroleum** or **natural gas**.

The unpleasant aspect of this trend is that coal is a relatively dirty fuel. When burned, it releases particulates and pollutants such as **carbon monoxide**, **nitrogen** and sulfur oxides into the **atmosphere**. If the use of coal is to expand continually, something must be done to reduce the hazard its use presents to the **environment**.

Over the past two decades, therefore, there has been an increasing amount of research on clean coal technologies, methods by which the **combustion** of coal releases fewer pollutants to the atmosphere. As early as 1970, the United States Congress acknowledged the need for such technologies in the **Clean Air Act** of that year. One provision of that Act required the installation of **flue gas** desulfurization (FGD) systems ("scrubbers") at all new coal-fired plants.

More than a dozen different technologies are now available on at least an experimental basis for the cleaning of coal. Some of these technologies are used on coal before it is even burned. Chemical, physical, and biological methods have all been developed for pre-combustion cleaning. For example, pyrite (FeS_2) is often found in conjunction with coal when it is mined. When the coal is burned, pyrite is also oxidized, releasing **sulfur dioxide** to the atmosphere. Yet pyrite can be removed from coal by rather simple, straightforward physical means because of differences in the densities of the two substances.

Biological methods for removing sulfur from coal are also being explored. The bacterium *Thiobacillus ferrooxidans* has the ability to change the surface properties of pyrite particles, making it easier to separate them from the coal itself. The bacterium may also be able to extract sulfur that is chemically bound to **carbon** in the coal.

A number of technologies have been designed to modify existing power plants to reduce the release of pollutants produced during the combustion of coal. In an attempt to improve on traditional wet **scrubbers**, researchers are now exploring the use of dry injection as one of these technologies. In this approach, dry compounds of calcium, sodium, or some other element are sprayed directly into the furnace or into the ducts downstream of the furnace. These compounds react with non-metallic oxide pollutants, such as sulfur dioxide and nitrogen dioxide, forming solids that can be removed from the system. A variety of technologies are being developed especially for the release of oxides of nitrogen. Since the amount of this pollutant formed is very much dependent on combustion temperature, methods of burning coal at lower temperatures are also being explored.

Some entirely new technologies are also being developed for installation in power plants to be built in the future. **Fluidized bed combustion**, integrated gasification combined cycle, and improved coal pulverization are three of these. In the first of these processes, coal and limestone are injected into a stream of upward-flowing air, improving the degree of oxidation during combustion. In the second process, coal is converted to a gas that can be burned in a conventional power plant. The third process involves improving on a technique that has long been used in power plants, reducing coal to very fine particles before it is fed into the furnace.

Clean Water Act (1972, 1977, 1987)

Federal involvement in protecting the nation's waters began with the **Water Pollution** Control Act of 1948, the first statute to provide state and local governments with the funding to address water **pollution**. During the 1950s and 1960s, awareness grew that more action was needed and federal funding to state and local governments was increased. In the **Water Quality** Act of 1965 **water quality standards**,

to be developed by the newly created Federal Water **Pollution Control** Administration, became an important part of federal water pollution control efforts.

Despite these advances, it was not until the Water Pollution Control Amendments of 1972 that the federal government assumed the dominant role in defining and directing water pollution control programs. This law was the outcome of a battle between Congress and President Richard M. Nixon. In 1970, facing a presidential re-election campaign, Nixon responded to public outcry over pollution problems by resurrecting the Refuse Act of 1899, which authorized the U.S. **Army Corps of Engineers** to issue **discharge** permits. Congress felt its prerogative to set national policy had been challenged. It debated for nearly 18 months to resolve differences between the House and Senate versions of a new law, and on October 18, 1972, Congress overrode a presidential veto and passed the Water Pollution Control Amendments.

Section 101 of the new law set forth its fundamental goals and policies, which continue to this day "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters." This section also set forth the national goal of eliminating discharges of pollution into navigable waters by 1985 and an interim goal of achieving water quality levels to protect fish, shellfish, and **wildlife**. As national policy, the discharge of toxic pollutants in toxic amounts was now prohibited; federal financial assistance was to be given for constructing publicly owned waste treatment works; area-wide pollution control planning was to be instituted in states; research and development programs were to be established for technologies to eliminate pollution; and **nonpoint source** pollution—runoff from urban and rural areas—was to be controlled. Although the federal government set these goals, states were given the main responsibility for meeting them, and the goals were to be pursued through a permitting program in the new **national pollutant discharge elimination system** (NPDES).

Federal grants for constructing publicly owned treatment works (POTWs) had totalled $1.25 billion in 1971, and they were increased dramatically by the new law. The act authorized five billion dollars in fiscal year 1973, six billion for fiscal year 1974, and seven billion for fiscal year 1975, all of which would be automatically available for use without requiring Congressional appropriation action each year. But along with these funds, the act conferred the responsibility to achieve a strict standard of secondary treatment by July 1, 1977. Secondary treatment of sewage consists of a biological process that relies on naturally occurring bacteria and other micro-organisms to break down organic material in sewage. The **Environmental Protection Agency** (EPA) was mandated to publish guidelines on secondary treatment within 60 days after passage of the law. POTWs also had to meet a July 1, 1983, deadline for a stricter level of treatment described in the legislation as "best practicable **wastewater** treatment." In addition, pretreatment programs were to be established to control industrial discharges that would either harm the treatment system or, having passed through it, pollute receiving waters.

The act also gave polluting industries two new deadlines. By July 1, 1977, they were required to meet limits on the pollution in their discharged **effluent** using Best Practicable Technology (BPT), as defined by EPA. The conventional pollutants to be controlled included **organic waste**, **sediment**, **acid**, bacteria and viruses, nutrients, oil and grease, and heat. Stricter state water quality standards would also have to be met by that date. The second deadline was July 1, 1983, when industrial dischargers had to install **Best Available Control Technology** (BAT), to advance the goal of eliminating all pollutant discharges by 1985. These BPT and BAT requirements were intended to be "technology forcing," as envisioned by the Senate, which wanted the new water law to restore water quality and protect ecological systems.

On top of these requirements for conventional pollutants, the law mandated the EPA to publish a list of toxic pollutants, followed six months later by proposed effluent standards for each substance listed. The EPA could require **zero discharge** if that was deemed necessary. The zero discharge provisions were the focus of great controversy when Congress began oversight hearings to assess implementation of the law. Leaders in the House considered the goal a target and not a legally binding requirement. But Senate leaders argued that the goal was literal and that its purpose was to ensure rivers and streams ceased being regarded as components of the waste treatment process. In some cases, the EPA has relied on the Senate's views in developing effluent limits, but the controversy over what zero discharge means continues to this day.

The law also established provisions authorizing the Army Corps of Engineers to issue permits for discharging dredge or fill material into navigable waters at specified disposal sites. In recent years this program, a key component of federal efforts to protect rapidly diminishing **wetlands**, has become one of the most explosive issues in the Clean Water Act. Farmers and developers are demanding that the federal government cease "taking" their private property through wetlands regulations, and recent sessions of Congress have been besieged with demands for revisions to this section of the law.

In 1977, Congress completed its first major revisions of the Water Pollution Control Amendments (which was renamed the "Clean Water Act"), responding to the fact that by July 1, 1977 only 30 percent of major municipalities were complying with secondary treatment requirements.

Moreover, a National Commission on Water Quality had issued a report which recommended that zero discharge be redefined to stress **conservation** and **reuse** and that the 1983 BAT requirements be postponed for five to ten years. The 1977 Clean Water Act endorsed the goals of the 1972 law, but granted states broader authority to run their construction grants programs. The act also provided deadline extensions and required EPA to expand the lists of pollutants it was to regulate.

In 1981, Congress found it necessary to change the construction grants program; thousands of projects had been started, with $26.6 billion in federal funds, but only 2,223 projects worth $2.8 billion had been completed. The Construction Grant Amendments of 1981 restricted the types of projects that could use grant money and reduced the amount of time it took for an application to go through the grants program.

The Water Quality Act of 1987 phased out the grants program by fiscal year 1990, while phasing in a state revolving loan fund program through fiscal year 1994, and thereafter ending federal assistance for wastewater treatment. The 1987 act also laid greater emphasis on toxic substances; it required, for instance, that the EPA identify and set standards for toxic pollutants in sewage **sludge**, and it phased in requirements for stormwater permits. The 1987 law also established a new toxics program requiring states to identify "toxic hot spots"—waters that would not meet water quality standards even after technology controls have been established—and mandated additional controls for those bodies of water.

These mandates greatly increased the number of NPDES permits that the EPA and state governments issued, stretching budgets of both to the limit. Moreover, states have billions of dollars worth of wastewater treatment needs that remain unfunded, contributing to continued violations of water quality standards. The new permit requirements for stormwater, together with sewer overflow, sludge, and other permit requirements, as well as POTW construction needs, led to a growing demand for more state flexibility in implementing the clean water laws and for continued federal support for wastewater treatment. State and local governments insist that they cannot do everything the law requires; they argue that they must be allowed to assess and prioritize their particular problems.

Yet despite these demands for less prescriptive federal mandates, on May 15, 1991, a bipartisan group of senators introduced the Water Pollution Prevention and Control Act to expand the federal program. The proposal was eventually set aside after intense debate in both the House and Senate over controversial wetlands issues. Amendments to the Clean Water Act proposed in both 1994 and 1995 also failed to make it to a vote.

In 1998, President Clinton introduced a Clean Water Action Plan, which primarily focused on improving compliance, increasing funding, and accelerating completion dates on existing programs authorized under the Clean Water Act. The plan contained over 100 'action items' that involved interagency cooperation of EPA, **U.S. Department of Agriculture** (USDA), Army Corps of Engineers, Department of the Interior, Department of Energy, **Tennessee Valley Authority**, Department of **Transportation**, and the Department of Justice. Key goals were to control nonpoint pollution, provide financial incentives for conservation and stewardship of private lands, restore wetlands, and expand the public's 'right to know' on water pollution issues.

New rules were proposed in 1999 to strengthen the requirements for states to set limits for and monitor the Total Maximum Daily Load (TMDL) of pollution in their waterways. The TMDL rule has been controversial, primarily because states and local authorities lack the funds and resources to carry out this large-scale project. In addition, agricultural and forestry interests, who previously were not regulated under the Clean Water Act, would be affected by TMDL rules. As of May 2002, the Bush administration has delayed the rule for further review.

In May 2002 the EPA announced a new rule changing the definition of "fill material" under the Clean Water Act to allow dirt, rocks, and other displaced material from mountaintop **coal** mining operations to be deposited into rivers as waste under permit from the Army Corps of Engineers, a practice that was previously unlawful under the Clean Water Act. Shortly thereafter, a group of congressional representatives introduced new legislation to overturn this rule, and a federal district court judge in West Virginia ruled that such amendments to the Clean Water Act could only be made by Congress, not by an EPA rule change. Whether or not the fill material rule will remain part of the Act remains to be seen.

As the Federal Water Pollution Control Act marks its thirtieth anniversary, the EPA state and federal regulators are increasingly recognizing the need for a more comprehensive approach to water pollution problems than the current system, which focuses predominantly on POTWs and industrial facilities. Nonpoint source pollution, caused when rain washes pollution from farmlands and urban areas, is the largest remaining source of water quality impairment, yet the problem has not received a fraction of the regulatory attention addressed to industrial and municipal discharges. Despite this fact, the EPA claims that the Clean Water Act is responsible for a one billion ton decrease in annual **soil runoff** from farming, and an associated reduction in **phosphorus** and **nitrogen** levels in water sources. EPA also asserts that wetland loss, while still a problem, has slowed significantly—from 1972 levels of 460,000 acres per year to

current losses of 70,000-90,000 annually. However, critics question these figures, citing abandoned mitigation projects and reclaimed wetlands that bear little resemblance to the **habitat** they are supposed to replicate. *See also* Agricultural pollution; Environmental policy; Industrial waste treatment; Sewage treatment; Storm runoff; Urban runoff

Clear-cutting

Webster's Dictionary defines clear-cutting as "removal of all the trees in a stand of timber." This **forest management** technique has been used in a variety of forests around the world. For many years, it was considered the most economical and environmentally sound way of harvesting timber. Since the 1960s and 1970s, the practice has been increasingly called into question as more has been learned about the ecological benefits of old growth timber especially in the Pacific Northwest of the United States and the global ecological value of tropical rain forests.

Foresters and loggers point out that there are practical economic and safety reasons for the practice of clear-cutting. For example, in the Pacific Northwest, these reasons revolve around the volume of wood that is present in the old growth forests. This volume can actually be an obstacle at times to harvesting, so that the most inexpensive way to remove the trees is to cut everything.

During the post-World War II housing boom in the 1950s, clear-cutting overtook selective cutting as the preferred method for harvesting in the Pacific Northwest. Since that time, worldwide demand for lumber has continued to rise. Practical arguments that the practice should continue despite its ecological implications are tied directly to the volume and character of the forest itself. Wood in temperate climates decays slowly, resulting in a large number of fallen logs—making even walking difficult, much less dragging cut trees to areas where they can be hauled to mills. Tall trees with narrow branch structures produce a lot of stems in a small area, therefore, the total **biomass** (or total input of living matter) in these temperate forests is typically four times that of the densest **tropical rain forest**. Some redwood forest groves in California have been measured with 20 times the biomass of similar sites in the tropics. Those supporting the harvest of these trees and clear-cutting point out that if these trees are not used, it will put increased pressure on other timber producers throughout the world to supply this wood. This could have high environmental costs globally, since it could take 10–30 acres (4–12 ha) of **taiga** forest in northern Canada, Alaska, or Siberia to produce the wood obtainable from one acre in the state of Washington.

Clear-cutting makes harvesting these trees very lucrative. The number of trees and downed logs makes it difficult to cut only some of the trees, and falling trees can damage the survivors; in addition, they can be damaged when dragged across the ground to be loaded onto trucks. This is made more expensive and time consuming by working around the standing trees. In areas that have been selectively logged, the trees left standing are may be knocked down by winds or may drop branches, presenting a considerable safety risk to loggers working in the area.

Old growth forests leave so much woody debris and half-decayed logs on the ground that it can be difficult to walk through a harvested patch to plant seedlings. This is why an accepted part of the clear-cut practice in the past has been to burn the leftover **slash**, after which seedlings are planted. Brush that grows on the site is treated with **herbicide** to allow the seedlings time to grow to the point at which they can compete with other vegetation.

Supporters of clear-cutting contend that it has unique advantages: burning consumes fuel that would otherwise be available to feed forest fires; **logging** roads built to haul the trees out open the forests to recreational uses and provide firebreaks; clear-cutting leaves no snags or trees to interfere with reseeding the forest, and allows use of helicopters and planes to spray herbicides—the brush that grows up naturally in the sunlight and provides browse for big-game **species** such as deer and elk.

Detractors point to a number of very negative environmental and economic consequences that need to be considered: particularly where clear cuts have been done near urban areas, plumes of **smoke** produced by burning slash have polluted cities; animal browse is choked out after a few years

An aerial view of a clear-cut area snaking its way through a South African forest (Photograph by Marco Polo. Phototake. Reproduced by permission.)

by the new seedlings, creating a darkened forest floor that lacks almost any vegetation or **wildlife** for at least three decades; herbicides applied to control vegetation contribute to the degradation of surface **water quality**; mining the forest causes declines in species diversity and loss of habitats (declaration of the **northern spotted owl** as an **endangered species** and the efforts to preserve its **habitat** is an example of the potential loss of diversity); new microclimates appear that promote less desirable species than the trees they replace; so much live and rotting wood is harvested or burned that the **soil** fertility is reduced, affecting the potential for future tree growth.

Critics also point out that **erosion** and **flooding** increases from clear-cut areas have significant economic impact downstream in the watersheds. Studies have shown that since the clear-cut practice increased following World War II, landslides have increased to six times the previous rate. This has resulted in increased **sediment** delivery to rivers and streams where it has a detrimental impact on the stream fishery.

Loss of **critical habitat** for endangered species such as the spotted owl and the impact of sediment on the **salmon** fishery have resulted in government efforts to set aside old growth forest **wilderness** to preserve the unique forest **ecosystem**. The practice of clear-cutting with its pluses and minuses, however, continues not only in the Pacific Northwest, but in other forests in the United States and in other areas of the world.

Clear-cutting and rain forests

Another area where clear-cutting has become the focus of ecological debate is in the tropical rain forests. Many of the same economic pressures that make clear-cutting a lucrative practice in the United States make it equally attractive in the **rain forest**, but there are significant environmental consequences.

Since 1960, the world demand for wood has increased by 90%, and as indicated above, the pressure to supply lumber to meet this demand has also increased. Nearly one-half of the Earth's rain forests have been cut in the last 30 years.

Besides the demand for building material or fuel, these forests are also subject to significant clearing to later be worked to produce food in new agricultural areas and to facilitate the exploration for oil and minerals. If this loss continues at present estimated rates, the rain forests will be totally harvested by the year 2040.

Rain forest activists continually work to remind the world of the importance of the forests. Locally, for instance, the presence or absence of the rain forest can change the **climate** and the local water budget. For example, times of **drought** are more severe and when the rains come, flooding is increased. As well, rain forests can have a major impact on the global climate. When they are cut and the slash burned, significant amounts of **carbon dioxide** are released into the **atmosphere**, which may contribute to the overall **greenhouse effect** and general warming of the earth.

The biological diversity of these forest ecosystems is vast. Rain forests contain about one-half the known plant and animal species in the world and very few of these species have ever been studied by scientists for their potential benefits. (More that 7,000 medicines have already been derived from tropical plants. It is uncertain how many more such uses are yet to be found.)

Most rain forests occur in less-developed countries where it is difficult to meet the expanding needs of rapidly increasing populations for food and shelter. They need the economic benefits that can be derived from the rain forest for their very survival. Any attempt at stopping the clear-cutting practice must provide for their needs to be successful. Until a better practice is developed, clear-cutting will remain an environmental issue on a global scale for the next several decades.

Frederic E. Clements (1874 – 1945)

American ecologist

For Frederick Clements, trained in botany as a plant physiologist, ecology became "the dominant theme in the study of plants, indeed...the central and vital part of botany." He became a leader in the new science, still described as "the leading plant ecologist of the day."

Clements was born in Lincoln, Nebraska, and earned all of his degrees in botany from the University of Nebraska, attaining his Ph.D. under Charles Bessey in 1989. As a student, he participated in Bessey's famous "Botanical Seminar" and helped carry out an ambitious survey of the vegetation of Nebraska, publishing the results—co-authored with a class-mate—in an internationally recognized volume titled The Phytogeography of Nebraska, out in print the same year (1898) that he received his doctorate. He then accepted a faculty position at the university in Lincoln.

Clements married Edith Schwartz in 1899, described (in Ecology in 1945) as a wife and help-mate, who "unsparingly devoted her unusual ability as an illustrator, linguist, and botanist" to become his life-long field assistant and also a collaborator on research and books on flowers, particularly those of the Rocky Mountains. Clements rose through the ranks as a teacher and researcher at Nebraska and then, in 1907, he was appointed as Professor and Head of the department of botany at the University of Minnesota. He stayed there until 1917, when he moved to the Carnegie Institution in Washington, D.C., where he focused full-time on research for the rest of his career. Retired from Carnegie in 1941, he continued a year-round work-load in research, spending summers on Pikes Peak at an alpine laboratory and winters in Santa Barbara at a coastal laboratory. He died in Santa Barbara on July 26, 1945.

Publication of Research Methods in Ecology in 1905 marked his promotion to full professor at the University of Nebraska, but more importantly it marked his turn from taxonomic and phytogeographical work to ecology. It has been called "the earliest how-to book in ecology," and "a manifesto for the emerging field." More broadly, Arthur Tansley, a leading plant ecologist of the time in Great Britain, though critical of some of Clements' views, described him as "by far the greatest individual creator of the modern science of vegetation." Henry a. Gleason, though an early and severe critic of Clements' ideas, also recognized him as "an original ecologist, one inspired by Europeans but developing his ideas entirely de novo from his own fertile brain."

Clements deplored the "chaotic and unsystematized" state of ecology and assumed the task of remedying it. He did bring rigor, standardization, and an early quantitative approach to research processes in plant ecology, especially through his development of sampling procedures at the turn of the century. Robert McIntosh, writing on the background of ecology, argues that Clements was the "pioneer in developing the quadrat as the basis of quantitative community ecology," was "an earnest cheerleader for quantitative plant ecology, and was the notable American developer and advocate of the quadrat method," though he also declares that "Clements did not get beyond simple counting, and more sophisticated statistical considerations were left to others." However, McIntosh still credits Clements' work as a giant step to quantification in ecology, the crux being that Clem-

ents methods "were designed to examine and follow change in vegetation, not only to report the status quo."

Clements is often described as rigid and dogmatic, which seems at odds with his importance in emphasizing change in natural systems; that emphasis on what he called "dynamic ecology" became his research trademark. Clements also stressed the importance of process and function. Clements anticipated ecosystem ecology through his concern for changes through time of plant associations, in correspondence to changes in the physical sites where the communities were found. His rudimentary conception of such systems carried his ecological questions beyond the traditional confines of plant ecology to what McIntosh described as "the larger system transcending plants, or even living organisms" to link to the abiotic environment, especially climate. McIntosh also credits him with a definition of paleoecology that antedated major developments that would studies of vegetation and pollen analysis (or palynology). Clements being Clements, he went into print with a book, Methods and Principles of Paleo-Ecology (1924) appropriate to the new topic. Clements even played a role, if not a major one relative to figures like Forbes, toward understanding what ecologists came to call eutrophic changes in lakes, an area of major current consideration in the environmental science of water bodies.

One of the stimulants for botanical, and then plant ecological, research for Clements and other students of Bessey's at Nebraska was their location in a major agricultural area dependent on plants for crops. Problems of agriculture remained one of Clements' interests for all of his life. During his long career, Clements remained continually involved in various ways of applying ecology to problems of land use such as grazing and soil erosion, even the planning of shelter belts. In large part because of the early work by Bessey and Clements and their colleagues and collaborators, the Midwest became a center for the development of grassland ecology and range management. Worster (in Nature's Economy, 1994) suggests that Clements' "dynamic ecology provided much of the scientific authority for the new ecological conservation movement" which, from the 1930's on, relied heavily on his "climax theory as a yardstick by which man's intrusions into nature could be measured." Though considered misguided by some, pleas for wilderness set-asides still argue today that land-use policy should leave "the climax" undisturbed or preserved areas returned to a perceived climax condition. Clements believed early that homesteaders in Nebraska were wrong to destroy the sod covering the sandhills of Nebraska and that the prairies should be grazed and not tilled. Farmers objected early to the implications of climax theory because they feared threats to their livelihoods from calls for cautious use of marginal lands. Even some scientific attempts to discredit the idea of the climax were based on the desire to undermine its importance to the conservation movement.

Clements even anticipated a century of sporadic connections between biological ecology and human ecology in the social sciences, arguing that sociology "is the ecology of a particular species of animal and has, in consequence, a similar close association with plant ecology." That connection was lost in in professional ecology in the early forties and has still not been reestablished, even at the beginning of the twenty-first century. Though Clements' name is still recognized today as one of ecology's foundation thinkers, and though he gained considerable respect and influence among the ecologists of his day, his work from the beginning was controversial. One reason was that ecologists were skeptical that approaches from plant physiology could be transposed directly to ecology. Another reason, and the idea with which Clements is still associated three-quarters of a century later, was his conviction that the successional process was the same as the development of an organism and that the communities emerging as the end-points of succession were in fact super-organisms. Clements believed that succession was a dynamic process of 'progressive' development of the plant formation, that it was controlled absolutely by climate, developed in an absolutely predictable way (and in the same way in all similar climates) and then was absolutely stable for long periods of time. A cautionary note from MacIntosh: "Clements's ideas are notably resilient and persist, often under different names," even "some of his suspect ideas persist in the new ecology under new rubrics." Synonymizing Gaia with a super organism is one frequently cited example.

Clements' fondness for words, and especially for coining his own nonce terms for about every conceivable nuance of his work also got him in trouble with his colleagues in ecology. As McIntosh terms it, Clements was known for his "labyrinthine logic and proliferation of terminology," characterized by others as "chronic logorrhea." This fondness for coining new words to describe his work, e.g., 'therium' to describe a successional stage caused by animals, added to the fuel for critics who wished to find fault with the substance of his ideas. Unfortunately, Clements also gave further cause to those, then and now, wishing to discount all of his ideas by retaining a belief in Lamarckian evolution, and by doing experiments during retirement at his alpine research station, in which he even claimed he been able to convert "several Linnean species into each other, histologically as well as morphologically."

Kingsland, writing in 1991, in Foundations of Ecology, identified Clements' 1936 article "The Nature and Structure of the Climax" as a classic paper and included its author as among those who defined ecology, but she could still claim that "by the 1950s plant ecologists had abandoned

many of the central principles of Clementsian dogma, as well as the more cumbersome features of his classification system, as inappropriate or unproductive." But without the work and thinking of the early ecologists that created a foundation on which to build, ecology might be considerably the lesser today. Missteps certainly were made, but the stones were laid and some of that foundation is based on the dynamics of ecological processes as first conceived by Clements in a considerable body of pioneering work.

Climate

Climate is the general, cumulative pattern of regional or global weather patterns. The most apparent aspects of climate are trends in air temperature and humidity, wind, and precipitation. These observable phenomena occur as the **atmosphere** surrounding the earth continually redistributes, via wind and evaporating and condensing water vapor, the energy that the earth receives from the sun.

Although the climate remains fairly stable on the human time scale of decades or centuries, it fluctuates continuously over thousands or millions of years. A great number of variables simultaneously act and react to create **stability** or fluctuation in this very complex system. Some of these variables are atmospheric composition, rates of **solar energy** input, **albedo** (the earth's reflectivity), and terrestrial geography. Extensive research helps explain and predict the behavior of individual climate variables, but the way these variables control and respond to each other remains poorly understood. Climate behavior is often likened to "chaos," changes and movements so complex that patterns cannot be perceived in them, even though patterns may exist. Nevertheless, studies indicate that human activity may be disturbing larger climate trends, notably by causing global warming. This prospect raises serious concern because rapid **anthropogenic** climate change could severely stress ecosystems and **species** around the world.

Solar energy and climate

Solar energy is the driving force in the earth's climate. Incoming radiation from the sun warms the atmosphere and raises air temperatures, warms the earth's surface, and evaporates water, which then becomes humidity, rain, and snow. The earth's surface reflects or re-emits energy back into the atmosphere, further warming the air. Warming air expands and rises, creating convection patterns in the atmosphere that reach over several degrees of latitude. In these convection cells, low pressure zones develop under rising air, and high pressure zones develop where that air returns downward toward the earth's surface. Such differences in atmospheric pressure force air masses to move, from high to low pressure regions. Movement of air masses creates wind on the earth's surface. When these air masses carry evaporated water, they may create precipitation when they move to cooler regions.

The sun's energy comes to the earth in a spectrum of long and short radiation wavelengths. The shortest wavelengths are microwaves and infrared waves. Infrared radiation is felt as heat. A small range of medium wavelength radiation makes up the spectrum of visible light. Longer wavelengths include ultraviolet (UV) radiation and radio waves. These longer wavelengths cannot be sensed, but UV radiation can cause damage as organic tissues (such as skin) absorb them. The difference in wavelengths is important because long and short wavelengths react differently when they encounter the earth and its atmosphere.

Solar energy approaching the earth encounters **filters**, reflectors, and absorbers in the form of atmospheric gases, clouds, and the earth's surface. Atmospheric gases filter incoming energy, selectively blocking some wavelengths and allowing other wavelengths to pass through. Blocked wavelengths are either absorbed and heat the air or scattered and reflected back into space. Clouds, composed of atmospheric water vapor, likewise reflect or absorb energy but allow some wavelengths to pass through. Some energy reaching the earth's surface is reflected; a great deal is absorbed in heating the ground, evaporating water, and conducting **photosynthesis**. Most energy that the earth absorbs is re-emitted in the form of short, infrared wavelengths, which are sensed as heat. Some of this heat energy circulates in the atmosphere for a time, but eventually it all escapes. If this heat did not escape, the earth would overheat and become uninhabitable.

Variables in the climate system

Climate responds to conditions of the earth's energy filters, reflectors, and absorbers. As long as the atmosphere's filtering effect remains constant, the earth's reflective and absorptive capacities do not change, and the amount of incoming energy does not vary, climate conditions should stay constant. Most of the time, though, some or all of these elements fluctuate. The earth's reflectivity changes as the

shapes, surface features, and locations of continents change. The atmosphere's composition changes from time to time, so that different wavelengths are reflected or pass through. The amount of energy the earth receives also shifts over time.

During the course of a decade the rate of solar energy input varies by a few watts per square meter. Changes in energy input can be much greater over several millennia. Energy intensity also varies with the shape of the earth's orbit around the sun. In a period of 100 million years the earth's elliptical orbit becomes longer and narrower, bringing the earth closer to the sun at certain times of year, then rounder again, putting the earth at a more uniform distance from the sun. When the earth receives relatively intense energy, heating and evaporation increase. Extreme heating can set up exaggerated convection currents in the atmosphere, with extreme low pressure areas receiving intensified rains and high pressure areas experiencing extreme **drought**.

The earth's albedo depends upon surface conditions. Extensive dark forests absorb a great deal of energy in heating, evaporation of water, and photosynthesis. Light, colored surfaces, such as **desert** or snow, tend to absorb less energy and reflect more. If highly reflective continents are large or are located near the equator, where energy input is great, then they could reflect a great deal of energy back into the atmosphere and contribute to atmospheric heating. However, if those continents are heavily vegetated, their reflective capacity might be lowered.

Other features of terrestrial geography that can influence climate conditions are mountains and glaciers. Both rise and fall over time and can be high enough to interrupt wind and precipitation patterns. For instance, the growth of the Rocky Mountains probably disturbed the path of upper atmospheric winds known as the jet stream. In southern Asia, the Himalayas block humid air masses flowing from the south. Intense precipitation results on the windward side of these mountains, while the downwind side remains one of the driest areas on Erth.

Atmospheric composition is a climate variable that began to receive increased attention during the 1980s. Each type of gas molecule in the atmosphere absorbs a particular range of energy wavelengths. As the mix of gases changes, the range of wavelengths passing through the filter shifts. For instance, the gas **ozone** (O_3) selectively blocks long wave UV radiation. A drop in upper atmospheric ozone levels discovered in the late 1980s has caused alarm because harmful UV rays are no longer being intercepted as effectively before they reach the earth's surface. Water vapor and solid particulates (dust) in the upper atmosphere also block incoming energy. Atmospheric dust associated with ancient meteor impacts is widely thought responsible for climatic cooling that may have killed the earth's dinosaurs 65 million years ago. Climate cooling could occur today if bombs from a nuclear war threw high levels of dust into the atmosphere. With enough radiation blockage, global temperatures could fall by several degrees, a scenario known as **nuclear winter**.

A human impact on climate that is more likely than nuclear winter is global warming caused by increased levels of **carbon dioxide** (CO_2) in the upper atmosphere. Most solar energy enters the atmospheric system as long wavelengths and is reflected back into space in the form of short wavelength (heat) energy. **Carbon** dioxide blocks these short, warm wavelengths as they leave the earth's surface. Unable to escape, this heat energy remains in the atmosphere and keeps the earth warm enough for life to continue. However, many studies suggest that the burning of **fossil fuels** and **biomass** have raised atmospheric carbon dioxide levels. Rising CO_2 levels could trap excessive amounts of heat and raise global air temperatures to dangerous levels. This scenario is popularly known as the **greenhouse effect**. Extreme amounts of trapped heat could disturb precipitation patterns. Ecosystems could overheat, killing plant and animal species. Polar ice caps could melt, raising global ocean levels and threatening human settlements.

Increased anthropogenic production of other gases such as **methane** (CH_4) also contributes to atmospheric warming, but carbon dioxide has been a focus of concern because it is emitted in much greater volume.

No one knows how seriously human activity may be affecting the large and turbulent patterns of climate. Sometimes a very subtle event can have magnified repercussions in larger wind, precipitation, and pressure systems, disturbing major climate patterns for decades. In many cases the climate appears to have a self-stabilizing capacity—an ability to initiate internal reactions to a destabilizing event that return it to equilibrium. For example, extreme greenhouse heating should cause increased evaporation of water. Resulting clouds could block incoming sunlight, producing an overall cooling effect to counteract heating.

Furthermore, human influences work on climate within a context of continually changing natural conditions and events. On a geologic time scale, temperatures, precipitation, and ocean levels have fluctuated enormously. A long series of ice ages and warmer interglacial periods began 2.5 million years ago and may still be going on. The last glacial maximum, with low sea levels because of extreme ice volumes, ended only 18,000 years ago—an instant in the earth's climate history.

Natural fluctuations occur on a more human time scale, as well. A summer of extreme drought and high temperatures in the United States in 1988 brought threats of global warming to the public's attention, but the drought itself resulted from a temporary aberration in high altitude wind patterns that centered an unusually stable high pressure zone over the Midwest. This temporary departure from normal conditions

was simply part of the continual fluctuation within the chaotic climate system. Terrestrial events, such as the 1991 eruption of **Mount Pinatubo** in the Philippines, also cause large, natural disturbances in climate. Dust from its eruption reached the upper atmosphere and was distributed around the globe, blocking enough incoming solar radiation to temporarily cool global temperatures by about 1.8°F (1°C).

No one can yet predict with **precision** how climate variables will respond to human activity. The earth's climate is so complex that human alterations to the atmosphere (such as those caused by carbon dioxide **emission**) amount to an "experiment" having an unknown—and possibly life-threatening—outcome.

Climax (ecological)

Referring to a community of plants and animals that is relatively stable in its **species** composition and **biomass**, ecological climax is the apparent termination of directional succession—the replacement of one community by another. That the termination is only apparent means that the climax may be altered by periodic disturbances such as **drought** or stochastic disturbances such as volcanic eruptions. It may also change extremely slowly owing to the gradual immigration and emigration—at widely differing rates—of individual species, for instance following the retreat of ice sheets during the postglacial period. Often the climax is a shifting mosaic of different stages of **succession** in a more or less steady state overall, as in many climax communities that are subject to frequent fires. Species that occur in climax communities are mostly good competitors and tolerant of the effects (e.g., shade, root **competition**) of the species around them, in contrast to the opportunistic colonists of early successional communities. The latter are often particularly adapted for wide dispersal and abundant reproduction, leading to success in newly opened habitats where competition is not severe.

In a climax community, productivity is in approximate balance with **decomposition**. Biogeochemical cycling of inorganic nutrients is also in balance, so that the stock of **nitrogen**, **phosphorus**, calcium, etc., is in a more or less steady state.

Frederic E. Clements was the person largely responsible in the early twentieth century for developing the theory of the climax community. Clements regarded **climate** as the predominant determining factor, though he did recognize that other factors—for instance, fire—could prevent the establishment of the theoretical "climatic climax." Later ecologists placed more stress on interactions among several determining factors, including climate, **soil** parent material, **topography**, fire, and the **flora** and **fauna** able to colonize a given site.

Clod

A compact, coherent mass of **soil** varying in size from 0.39–9.75 in (10–250 mm). Clods are produced by operations like plowing, cultivation, and digging, especially on soils that are too wet or too dry. They are usually formed by compression, or by breaking off from a larger unit. Tractor attachments like disks, spike-tooth harrows, and rollers are used to break up clods during seedbed preparation.

Cloning

Cloning hit the news headlines in 1997 when scientists in Scotland announced they had successfully cloned a sheep, named Dolly, in 1996. Although several other animal **species** had been cloned in the previous 20 years, it was Dolly that caught the public's attention. Suddenly, the possibility that humans might soon be cloned jumped from the pages of science fiction stories into the mainstream press. Dolly was the first adult mammal ever cloned.

Cloning is the science of using artificial methods to create clones. A clone is a single cell, a group of cells, or an organism produced in a laboratory without sexual reproduction. In effect, the clone is an exact genetic copy of the original source, much like identical twins. There are two types of cloning. Blastomere separation, also called "twinning" after the naturally occurring process that creates identical twins, involves splitting a developing embryo soon after the egg is fertilized by sperm. The result is identical twins with DNA from both parents. The second cloning type, called nuclear transfer, is what scientists used to create Dolly.

In cloning Dolly, scientists transferred genetic material from an adult female sheep to an egg in which the nucleus containing its genetic material had been removed.

Simple methods of cloning plants, such as grafting and stem cutting, have been used for more than 2,000 years. The modern era of laboratory cloning began in 1958 when the English-American plant physiologist Frederick C. Steward cloned carrot plants from mature single cells placed in a **nutrient** culture containing hormones, **chemicals** that play various and significant roles in the body.

The first cloning of animal cells occurred in 1964. In the first step of the experiment, biologist John B. Gurdon destroyed with ultraviolet light the genetic information stored in a group of unfertilized toad eggs. He then removed the nuclei (the part of an animal cell that contains the genes) from intestinal cells of toad tadpoles and injected them into those eggs. When the eggs were incubated (placed in an **environment** that promotes growth and development), Gurdon found that 1–2% of the eggs developed into fertile, adult toads.

The first successful cloning of mammals was achieved nearly 20 years later. Scientists in both Switzerland and the United States successfully cloned mice using a method similar to that of Gurdon. However, the Swiss and American methods required one extra step. After the nuclei were taken from the embryos of one type of mouse, they were transferred into the embryos of another type of mouse. The second type of mouse served as a substitute mother that went through the birthing process to create the cloned mice. The cloning of cattle livestock was achieved in 1988 when embryos from cows were transplanted to unfertilized cow eggs whose own nuclei had been removed.

Since Dolly, the pace and scope of cloning mammals has greatly intensified. In February 2002, scientists at Texas A&M University announced they had cloned a cat, the first cloning of a common domestic pet. Named "CC" (for **carbon** copy or copycat), the cat is an exact genetic duplicate of a two–year–old calico cat. Scientists cloned CC in December 2001 using the nuclear transfer method. In April 2002, a team of French scientists announced they had cloned rabbits using the nuclear transfer process. Out of hundreds of embryos used in the experiment, six rabbits were produced, four that developed normally and two that died. Two of the cloned rabbits mated naturally and produced separate litters of seven and eight babies

The first human embryos were cloned in 1993 using the blastomere technique that placed individual embryonic cells (blastomeres) in a nutrient culture where the cells then divided into 48 new embryos. These experiments were conducted as part of some studies on in vitro (out of the body) fertilization aimed at developing fertilized eggs in test tubes that could then be implanted into the wombs of women having difficulty becoming pregnant. However, these fertilized eggs did not develop to a stage that was suitable for transplantation into a human uterus.

Research into cloning humans also picked up greatly following the success of Dolly. An Italian physician said in April 2002 that a woman was pregnant with what would be the world's first cloned human baby. The doctor, Severino Antinori, operates a fertility clinic near the Vatican in Rome. In March 2002, a Chinese researcher said she had cloned a human embryo to the blastocyst stage, the point at which stem cells can be harvested. Scientists in several other countries also are believed conducting human cloning experiments.

The cloning of cells promises to produce many benefits in farming, medicine, and basic research. In farming, the goal is to clone plants that contain specific traits that make them superior to naturally occurring plants. For example, field tests have been conducted using clones of plants whose genes have been altered in the laboratory by **genetic engineering** to produce **resistance** to insects, viruses, and bacteria. New strains of plants resulting from the cloning of specific traits have led to fruits and vegetables with improved nutritional qualities, longer shelf lives, and new strains of plants that can grow in poor **soil** or even under water.

A cloning technique known as twinning could induce livestock to give birth to twins or even triplets, thus reducing the amount of feed needed to produce meat. Cloning also holds promise for saving certain rare breeds of animals from **extinction**, such as the **giant panda**.

In medicine, gene cloning has been used to produce vaccines and hormones. Cloning techniques have already led to the inexpensive production of the hormone insulin for treating diabetes and of growth hormones for children who do not produce enough hormones for normal growth. The use of monoclonal antibodies in disease treatment and research involves combining two different kinds of cells (such as mouse and human **cancer** cells) to produce large quantities of specific antibodies. These antibodies are produced by the immune system to fight off disease. When injected into the blood stream, the cloned antibodies seek out and attack disease–causing cells anywhere in the body.

Despite the benefits of cloning and its many promising avenues of research, certain moral, religious, and ethical questions concerning the possible abuse of cloning have been raised. At the heart of these questions is the idea of humans tampering with life in a way that could harm society, either morally or in a real physical sense. Some people object to cloning because it allows scientists to "act like God" in manipulating living organisms.

The cloning of Dolly and the fact that some scientists are attempting to clone humans raised the debate over this practice to an entirely new level. A person could choose to

make two or 10 or 100 copies of himself or herself by the same techniques used with Dolly. This realization has stirred an active debate about the morality of cloning humans. Some people see benefits from the practice, such as providing a way for parents to produce a new child to replace one dying of a terminal disease. Other people worry about humans taking into their own hands the future of the human race.

Another controversial aspect of cloning deals not with the future but the past. Could Abraham Lincoln or Albert Einstein be recreated using DNA from a bone, hair, or tissue sample? If so, perplexing questions arise about whether this is morally or ethically acceptable? Some scientists say that while it might be possible to do this, the clone might be identical in appearance and in some traits, it would not have the same personality as the original Lincoln. This is because Lincoln, like all people, was greatly shaped from birth by his environment and personal experiences in addition to his genetic coding. Although a duplicate of her mother, CC, the cloned calico cat, has a different color pattern on her fur. This is because environmental factors strongly influence her development in the womb.

Also, since the movie "Jurassic Park" was released in 1993, there has been considerable public discussion about the possibility of cloning dinosaurs and other prehistoric or extinct species. In 1999, the Australian Museum in Sydney, **Australia**, announced scientists were attempting to clone a thylacine (a meat–eating marsupial related to kangaroos and opossums). It has been extinct since 1932 but the museum has the body of a baby thylacine that has been preserved for 136 years. The problem is that today's cloning techniques are possible only with living tissue. Even the head of the project has doubts, saying the chance of cloning a living thylacine is 30% over the next 200 years.

Cloud chemistry

One of the exciting new fields of chemical research in the past half century involves chemical changes that take place in the **atmosphere**. Scientists have learned that a number of reactions are taking place in the atmosphere at all times. For example, oxygen (O_2) molecules in the upper **stratosphere** absorb **solar energy** and are converted to **ozone** (O_3). This ozone forms a layer that protects life on Earth by filtering out the harmful **ultraviolet radiation** in sunlight. **Chlorofluorocarbons** and other chlorinated solvents (e.g., **carbon** tetrachloride and methyl chloroform) generated by human activities also trigger chemical reactions in the upper atmosphere including the break up of ozone into the two-atom form of oxygen. This reaction depletes the earth's protective ozone layer.

Clouds are often an important locus for atmospheric chemical reactions. They provide an abundant supply of water molecules that act as the solvent required for many reactions. An example is the reaction between **carbon dioxide** and water, resulting in the formation of carbonic **acid**. The abundance of both carbon dioxide and water in the atmosphere means that natural rain will frequently be somewhat acidic. Although conditions vary from time to time and place to place, the **pH** of natural, unpolluted rain is normally about 5.6. (The pH of pure water is 7.0). Other naturally occurring components of the atmosphere also react with water in clouds. In regions of volcanic activity, for example, **sulfur dioxide** released by outgassing and eruptions is oxidized to sulfur trioxide, which then reacts with water to form sulfuric acid.

The water of which clouds are composed also acts as solvent for a number of other chemical **species** blown into the atmosphere from the earth's surface. Among the most common ions found in solution in clouds are sodium (Na^+), magnesium (Mg^{2+}), chloride (Cl^-), and sulfate (SO_4^{2-}) from sea spray; potassium (K^+), calcium (Ca^{2+}), and carbonate (CO_3^{2-}) from **soil** dust; and ammonium (NH_4^+) from organic decay.

The nature of cloud chemistry is often changed as a result of human activities. Perhaps the best known and most thoroughly studied example of this involves **acid rain**. When **fossil fuels** are burned, sulfur dioxide and **nitrogen oxides** (among other products) are released into the atmosphere. Prevailing winds often carry these products for hundreds or thousands of miles from their original source. Once deposited in the atmosphere, these oxides tend to be absorbed by water molecules and undergo a series of reactions by which they are converted to acids. Once formed in clouds by these reactions, sulfuric and nitric acids remain in solution in water droplets and are carried to earth as fog, rain, snow, or other forms of precipitation.

Club of Rome

In April of 1968, 30 people, including scientists, educators, economists, humanists, industrialists, and government officials, met at the Academia dei Lincei in Rome. The meeting was called by Dr. Aurelio Peccei, an Italian industrialist and economist. The purpose of this meeting was to discuss "the present and future predicament of man." The "Club of Rome" was born from this meeting as an informal organization that has been described as an "invisible college." Its purpose, as described by Donella Meadows, is to foster understanding of the varied but interdependent components—economic, political, natural and social—that make up the global system in which we all live; to bring that new understanding to the attention of policy-makers and the public worldwide; and in this way to promote new policy initiatives and action. The original list of members is listed in the preface to Meadows's book entitled *The Limits to Growth*, in which the basic findings of the group are eloquently explained.

This text is a modern-day equivalent to the hypothesis of Thomas Malthus, who postulated that since increases in food supply cannot keep pace with geometric increases in human population, there would therefore be a time of **famine** with a stabilization of the human population. This eighteenth century prediction has, to a great extent, been delayed by the "green revolution" in which agricultural production has been radically increased by the use of fertilizers and development of special genetic strains of agricultural products. The high cost of **agricultural chemicals** which are generally tied to the price of oil has, however, severely limited the capability of developing nations to purchase them.

The development of the Club of Rome's studies is most potently presented by Meadows in the form of graphs which plot on a time axis the supply of **arable land** needed at several production levels (present, double present, quadruple present, etc.) to feed the world's population based upon growth models.

She states that 7.9 billion acres (3.2 billion ha) of land are potentially suitable for agriculture on the earth; half of that land, the richest and most accessible half, is under cultivation today. She further states that the remaining land will require immense capital inputs to reach, clear, irrigate, or fertilize before it is ready to produce food. One can imagine the impact such conversion will have on the **environment**.

The Club of Rome's studies were not limited to food supply but also considered industrial output per capita, **pollution** per capita, and general resources available per capita. The key issue is that the denominator, per capita, keeps increasing with time, requiring ever more frugal and careful use of the resources; however, no matter how carefully the resources are husbanded, the inevitable result of uncontrolled **population growth** is a catastrophe which can only be delayed. Therefore stabilizing the rate of world population growth must be a continuing priority.

As a follow-up to the Club of Rome's original meeting, a global model for growth was developed by Jay Forrester of the Massachusetts Institute of Technology. This model is capable of update with insertion of information on popula-

tion, agricultural production, **natural resources**, industrial production, and pollution. Meadows's report *The Limits to Growth* represents a readable summary of the results of this **modeling**.

A new branch of the Club of Rome is the TT30, a group of people around the age of 30 who form a "think tank." This group is primarily concerned with problems of today, future issues, and how to deal with them.

C:N ratio

Organic materials are composed of a mixture of carbohydrates, lignins, tannins, fats, oils, waxes, resins, proteins, minerals, and other assorted compounds. With the exception of the mineral fraction, the organic compounds are composed of varying ratios of **carbon** and **nitrogen**. This is commonly abbreviated to the C:N ratio. Carbohydrates are composed of carbon, **hydrogen**, and oxygen and are relatively easily decomposed to **carbon dioxide** and water, plus a small amount of other by-products. Protein-like materials are the prime source of nitrogen compounds as well as sources of carbon, hydrogen, and oxygen and are important to the development of the C:N ratio and the eventual **decomposition** rate of the organic materials.

The **aerobic** heterotrophic bacteria are primarily responsible for the decay of the large amount of organic compounds generated on the earth's surface. These organisms typically have a C:N ratio of about 8:1. When organic residues are attacked by the bacteria under appropriate **habitat** conditions, some of the carbon and nitrogen are assimilated into the new and rapidly increasing microbial population, and copious amounts of carbon dioxide are released to the **atmosphere**. The numbers of bacteria are highly controlled by the C:N ratio of the organic substrate.

As a rule, when organic residues of less than 30:1 ratio are added to a **soil**, there is very little noticeable decrease in the amount of mineral nitrogen available for higher plant forms. However as the C:N ratio begins to rise to values of greater than 30:1, there may be **competition** for the mineral nitrogen forms. Bacteria are lower in the **food chain/web** and become the immediate beneficiary of available sources of mineral nitrogen, while the higher **species** may suffer a lack of mineral nitrogen. Ultimately, when the carbon source is depleted, the organic nitrogen is released from the decaying **microbes** as mineral nitrogen.

The variation in the carbon content of organic material is reflected in the constituency of the compound. Carbohydrates usually contain less than 45% carbon, while lignin may contain more than 60% carbon. The C:N ratio of plant material may well reflect the kind and stage of growth of the plant. A young plant typically contains more carbohydrates and less lignin, while an older plant of the same species will contain more lignin and less carbohydrate. Ligneous tissue such as found in trees may have a C:N ratio of up to 1000:1.

The relative importance of the C:N ratio addresses two concerns: one, the rate of the organic matter decay to the low C:N ratio of **humus**, (approximately 10:1), and secondly the immediate availability of mineral nitrogen (NH_4^+) to meet the demand of higher plant needs. The addition of mineral nitrogen to organic residues is a common practice to enhance the rate of decay and to reduce the potential for nitrogen deficiency developing in higher plants where copious amounts of organic residue which has a C:N ratio of greater than 30:1 have been added to the soil.

Composting of organic residues permits the breakdown of the residues to occur without competition the of higher plants for the mineral nitrogen and also reduces the C:N ratio of the resulting mass to a C:N value of less than 20:1. When this material is added to a soil, there is little concern about the potential for nitrogen competition between the micro-organisms and the higher plants.

2000	4.51	548.47	88.74	433.78

Coal production from 1950 through 2000. MMst stands for million short tons.

Coal

Consisting of altered remains of plants, coal is a widely used fossil fuel. Generally, the older the coal, the higher the **carbon** content and heating value. Anthracite coal ranks highest in carbon content, then bituminous coal, subbituminous coal, and lignite (as determined by the American Society for Testing Materials). Over 80% of the world's vast reserves occur in the former Soviet Union, the United States, and China. Though globally abundant, it is associated with many environmental problems, including **acid drainage**, degraded land, sulfur oxide emissions, **acid rain**, and heavy **carbon dioxide** emissions. However, clean coal-burning technologies, including liquified or gasified forms, are now available.

Anthracite, or "hard" coal, differs from the less altered bituminous coal by having more than 86% carbon and less than 14% volatile matter. It was formerly the fuel of choice for heat purposes because of high **Btu** (British Thermal Unit) values, minimally 14,500, and low ash content. In the United States, production has dropped from 100 million tons in 1917 to about seven million tons as anthracite has been replaced by oil, **natural gas**, and electric heat. Predominantly in eastern Pennsylvania's Ridge and Valley Province, anthracite seams have a wavelike pattern, complicating extraction. High water tables and low demand are the main impediments to expansion.

Bituminous coal, or "soft" coal, is much more abundant and easier to mine than anthracite but has lower carbon content and Btu values and higher volatility. Historically dominant, it energized the Industrial Revolution, fueling steam engines in factories, locomotives, and ships. Major coal regions became steel centers because two tons of coal were needed to produce each ton of iron ore. This is the only coal suitable for making coke, needed in iron smelting processes. Major deposits include the Appalachian Mountains and the Central Plains from Indiana through Oklahoma.

Subbituminous coal ranges in Btu values from 10,500 (11,500 if agglomerating) down to 8,300. Huge deposits exist in Wyoming, Montana, and North Dakota with seams 70 ft (21.4 m) thick. Though distant from major utility markets, it is used extensively for electrical power generation and is preferred because of its abundance, low sulfur content,

and good grinding qualities. The latter makes it more useful than the higher grade, but harder, bituminous coal because modern plants spray the coal into **combustion** chambers in powder form. Demand for this coal skyrocketed following the 1973 OPEC **oil embargo** and subsequent restrictions on natural gas use in new plants.

Lignite, or "brown" coal, is the most abundant, youngest, and least mature of the coals, with some plant texture still visible. Its Btu values generally range below 8,300. Although over 70% of the deposits are found in North America, mainly in the Rocky Mountain region, there is little production there. It is used extensively in many eastern European countries for heating and steam production. Russian scientists have successfully burned lignite *in situ*, tapping the resultant coal gas for industrial heating. If concerns over global warming are satisfied, future liquefying and gasifying technologies could make lignite a prized resource.

Coal bed methane

Coal bed **methane** (CBM) is a **natural gas** contained in coal seams. Methane gas is formed during coalification, the transformation of plant material into coal. Also called coal seam gas, CBM is usually not found in the **atmosphere** until it is released during coal mining. The gas released during mining is called coal mine methane (CMM).

According to the United States **Environmental Protection Agency**, 88 billion cubic feet of CMM can provide electricity to more than 1.2 million homes for a year. CBM is another source of methane, which is also used to heat buildings.

At the start of the twenty-first century, CBM drilling was underway in states such as New Mexico, Colorado, Wyoming, and Montana. The gas is often located in aquifers, porous rock that contains water. Gas is obtained by pumping thousands of gallons of water out of a CBM well.

This process could negatively affect the **environment** because **groundwater** frequently contains salt and other minerals. Removed water is reinjected into the ground in New Mexico and Colorado. Reinjection is not always possible, which brings more environmental concerns. In 2002, Montana residents worried that groundwater released into rivers and streams could hurt crops, **wildlife**, and drinking water.

[*Liz Swain*]

Coal gasification

The term **coal** gasification refers to any process by which coal is converted into some gaseous form that can then be burned as a fuel. Coal gasification technology was relatively well known before World War II, but it fell out of favor after the war because of the low cost of oil and **natural gas**. Beginning in the 1970s, utilities showed renewed interest in coal gasification technologies as a way of meeting more stringent environmental requirements.

Traditionally, the use of **fossil fuels** in **power plants** and industrial processes has been fairly straight-forward. The fuel—coal, oil, or natural gas—is burned in a furnace and the heat produced is used to run a turbine or operate some industrial process. The problem is that such direct use of fuels results in the massive release of oxides of **carbon**, sulfur, and **nitrogen**, of unburned **hydrocarbons**, of **particulate** matter, and of other pollutants. In a more environmentally-conscious world, such reactions are no longer acceptable.

This problem became much more severe with the shift from oil to coal as the fuel of choice in power generating and industrial plants. Coal is "dirtier" than both oil and natural gas and its use, therefore, creates more serious and more extensive environmental problems.

The first response of utilities and industries to new **air pollution** standards was to develop methods of capturing pollutants after **combustion** has occurred. **Flue gas** desulfurization systems, called **scrubbers**, were one approach strongly favored by the United States government. But such systems are very expensive, and utilities and industries rapidly began to explore alternative approaches in which coal is cleansed of material that produce pollutants when burned. One of the most promising of these clean-coal technologies is coal gasification.

A variety of methods are available for achieving coal gasification, but they all have certain features in common. In the first stages, coal is prepared for the reactor by crushing and drying it and then pre-treating it to prevent caking. The pulverized coal is then fed into a boiler where it reacts with a hot stream of air or oxygen and steam. In the boiler, a complex set of chemical reactions occur, some of which are exothermic (heat releasing) and some of which are endothermic (heat-absorbing).

An example of an exothermic reaction is the following.

$$2\ C + {}^{3}/_{2}\ O_2 \rightarrow CO_2 + CO$$

The **carbon monoxide** produced in this reaction may then go on to react with **hydrogen** released from the coal to produce a second exothermic reaction.

$$CO + 3\ H_2 \rightarrow CH_4 + H_2O$$

The energy released by one or both of the reactions is then available to initiate a third reaction that is endothermic.

$$C + H_2O \rightarrow > CO + H_2$$

Finally, the mixture of gases resulting from reactions such as these, a mixture consisting most importantly of carbon monoxide, **methane**, and hydrogen, is used as fuel in a boiler that produces steam to run a turbine and a generator.

In practice, the whole series of exothermic and endothermic reactions are allowed to occur within the same vessel, so that coal, air or oxygen, and steam enter through one inlet in the boiler, coal enters at a second inlet, and the gaseous fuel is removed through an outlet pipe.

One of the popular designs for a coal gasification reaction vessel is the Lurgi pressure gasifier. In the Lurgi gasifier, coal enters through the top of a large cylindrical tank. Steam and oxygen are pumped in from the bottom of the tank. Coal is burned in the upper portion of the tank at relatively low temperatures, initiating the exothermic reactions described above. As unburned coal flows downward in the tank, heat released by these exothermic reactions raises the temperature in the tank and brings about the endothermic reaction in which carbon monoxide and hydrogen are produced. These gases are then drawn off from the top of the Lurgi gasifier.

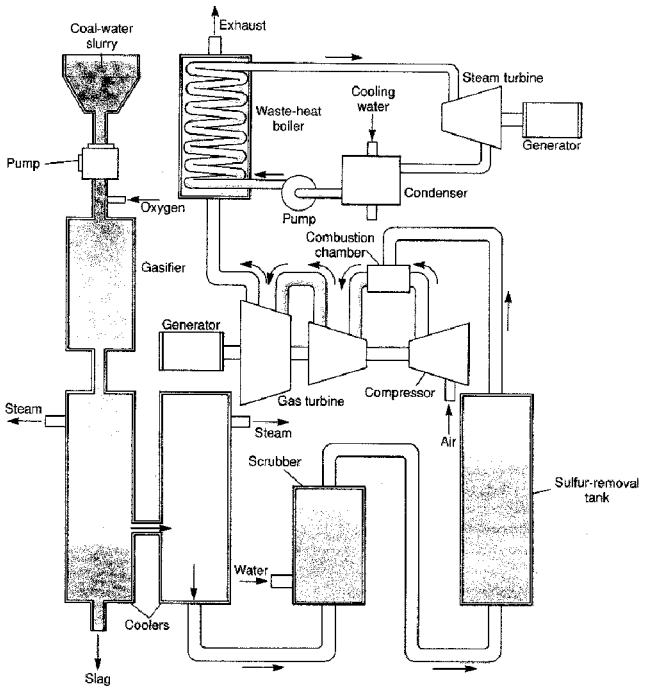
The exact composition of the gases produced is determined by the materials introduced into the tank and the temperature and pressure at which the boiler is maintained. One possible product, chemical synthesis gas, consists of carbon monoxide and hydrogen. It is used primarily by the chemical industry in the production of other **chemicals** such as ammonia and methyl alcohol. A second possible product is medium-Btu gas, made up of hydrogen and carbon monoxide. Medium-Btu gas is used as a general purpose fuel for utilities and industrial plants. A third possible product is substitute natural gas, consisting essentially of methane. Substitute natural gas is generally used as just that, a substitute for natural gas.

Coal gasification makes possible the removal of pollutants before the gaseous products are burned by a utility or industrial plant. Any ash produced during gasification, for example, remains within the boiler, where it settles to the bottom of the tank, is collected, and then removed. **Sulfur dioxide** and **carbon dioxide** are both removed in a much smaller, less expensive version of the scrubbers used in smokestacks.

Perhaps the most successful test of coal gasification technology has been going on at the Cool Water Integrated Gasification Combined Cycle plant near Barstow, California. The plant has been operating since June 1984 and is now capable of generating 100 megawatts of electricity. The four basic elements of the plant are a gasifier in which combustible gases are produced, a particulate and sulfur removal system, a combustion turbine in which the synthetic gas is burned, and a stem turbine run by heat from the combustion turbine and the gasifier.

The Cool Water plant has been an unqualified environmental success. It has easily met federal and state standards for **effluent** sulfur dioxide, oxides of nitrogen, and particulates, and its solid wastes have been found to be nonhazardous by the California Department of Health.

Waste products from the removal system also have commercial value. Sulfur obtained from the reduction of sulfur dioxide is 99.9% pure and has been selling for about $100 a ton. Studies are also being made to determine the possible use of slag for road construction and other building purposes.



Coal gasification appears to be a promising energy technology for the twenty-first century. One of the intriguing possibilities is to use sewage or hazardous wastes in the primary boiler. In the latter case, hazardous elements could be fixed in the slag drawn off from the bottom of the boiler, preventing their contaminating the final gaseous product.

The major impediment in the introduction of coal gasification technologies on a widespread basis is their cost. At the present time, a plant operated with synthetic gas from a coal gasification unit is about three times as expensive as a comparable plant using natural gas. Further research is obviously needed to make this new technology economically competitive with more traditional technologies.

Another problem is that most coal gasification technologies require very large quantities of water. This can be an especially difficult problem since gasification plants should be built near mines to reduce shipping costs. But most mines are located in Western states, where water supplies are usually very limited.

Finally, coal gasification is an inherently less efficient process than the direct combustion of coal. In most approaches, between 30 and 40% of the heat energy stored in coal is lost during its conversion to synthetic gas. Such conversions would probably be considered totally unacceptable except for the favorable environmental trade-offs they provide.

A schematic of coal gasification by heating a coal-and-water slurry in a low-oxygen environment. (McGraw-Hill Inc. Reproduced by permission.)

One possible solution to the problem described above is to carry out the gasification process directly in underground coal mines. In this process, coal would be loosened by explosives and then burned directly in the mine. The low-grade synthetic gas produced by this method could then be piped out of the ground, upgraded and used as a fuel. Underground gasification is an attractive alternative for many reasons. By some estimates, up to 80% of all coal reserves cannot be recovered through conventional mining techniques. They are either too deep underground or dispersed too thinly in the earth. The development of methods for gasification in coal seams would, therefore, greatly increase the amount of this fossil fuel available for our use.

A great deal of research is now being done to make coal gasification a more efficient process. A promising breakthrough involves the use of potassium hydroxide or potassium carbonate as a catalyst in the primary reactor vessel. The presence of a catalyst reduces the temperature at which gasification occurs and reduces, therefore, the cost of the operation.

Governments in the United States and Europe, energy research institutes, and major energy corporations are actively involved in research on coal gasification technologies. The Electric Power Research Institute, Institute of Gas Technology, **U.S. Department of Energy**, Texaco, Shell, Westinghouse, and Exxon are all studying modifications in the basic coal gasification system to find ways of using a wide range of raw materials, to improve efficiency at various stages in the gasification process, and, in general, to reduce the cost of plant construction. *See also* Alternative fuels; Air pollution control; Air quality; Coal washing; Flue-gas scrubbing; Strip mining; Surface mining

Coal washing

Coal that comes from a mine is a complex mixture of materials with a large variety of physical properties. In addition to the coal itself, pieces of rock, sand, and various minerals are contained in the mixture. Thus, before coal can be sold to consumers, it must be cleaned. The cleaning process consists of a number of steps that results in a product that is specifically suited to the needs of particular consumers. Among the earliest of these steps is crushing and sizing, two processes that reduce the coal to a form required by the consumer.

The next step in coal preparation is a washing or cleaning step. This step is necessary not only to meet consumer requirements, but also to ensure that its **combustion** will conform to environmental standards.

Coal washing is accomplished by one of two major processes, by *density separation* or by *froth flotation*. Both processes depend on the fact that the particles of which a coal sample are made have different densities. When water, for example, is added to the sample, particles sink to various depths depending on their densities. The various components of the sample can thus be separated from each other.

In some cases, a liquid other than water may be used to achieve this separation. In a heavy medium bath, for example, a mineral such as magnetite or feldspar in finely divided form may be mixed with water, forming a liquid medium whose density is significantly greater than that of pure water.

A number of devices and systems have been developed for extracting the various components of coal once they have

been separated with a water or heavy medium treatment. One of the oldest of these devices is the *jig*. In a jig, the column of water is maintained in a constant up-and-down movement by means of a flow of air. Clean coal particles are carried to the top of the jig by this motion, while heavier refuse particles sink to the bottom.

Another method of extraction, the *cyclone*, consists of a tank in which the working fluid (water or a heavy medium) is kept in a constant circular motion. The tank is constructed so that lighter clean coal particles are thrown out of one side, while heavier refuse particles are ejected through the bottom.

Shaking tables are another extraction method. As the table shakes back and forth, particles are separated by size, producing clean coal at one end and waste products at the other.

In cylindrical separators, a coal mixture is fed into a spinning column of air that throws the heavier waste particles outward. They coat the inner wall of the cylinder and fall to the bottom, where they are drawn off. The clean coal particles remain in the center of the air column and are drawn off at the top of the cylinder.

Froth **flotation** processes depend on the production of tiny air bubbles to which coal particles adhere. The amount of **absorption** onto a bubble depends not only on a particle's density, but also on certain surface characteristics. Separation of clean coal from waste materials can be achieved in froth flotation by varying factors, such as **pH** of the solution, time of treatment, particle size and shape, rate of **aeration**, solution density, and bubble size.

Coase theorem

An economic theorem that is sometimes used in discussions of external costs in environment-related situations. The standard welfare economic view states that in order to make the market efficient, external costs—such as **pollution** produced by a company in making a product—should be internalized by the company in the form of taxes or fees for producing the pollution. Coase theorem, in contrast, states that the responsibility for the pollution should fall on both the producer and recipient of the pollution. For example, people who are harmed by the pollution can pay companies not to pollute, thereby protecting themselves from any potential harm.

Ronald Coase, the economist who proposed the theorem, further states that government should intervene when the bargaining process or transaction costs between the two parties is high. The government's role, therefore, is not to address external costs which harm bystanders but to help individuals organize for their protection.

Coastal Society, The

The Coastal Society (TCS), founded in 1975, is an international, nonprofit organization which serves as a forum for individuals concerned with problems related to coastal areas. Its members, drawn from university settings, government, and private industry, agree that the **conservation** of coastal resources demands serious attention and high priority.

TCS has four main goals: 1) to foster cooperation and communication among agencies, groups, and private citizens; 2) to promote conservation and intelligent use of coastal resources; 3) to strengthen the education and appreciation of coastal resources; and 4) to help government, industry, and individuals successfully balance development and protection along the world's coastlines. Through these goals, TCS hopes to educate the public and private sectors on the importance of effective coastal management programs and clear policy and law regarding the coasts.

Since its inception, TCS has sponsored numerous conferences and workshops. Individuals from various disciplines are invited to discuss different coastal problems. Past conferences have covered such topics as "Energy Across the Coastal Zone," "Resource Allocation Issues in the Coastal Environment," "The Present and Future of Coasts," and "Gambling with the Shore." Workshops are sponsored in conjunction with government agencies, universities, professional groups, and private organizations. Conference proceedings are subsequently published. TCS also publishes a quarterly magazine, *TCS Bulletin*, which features articles and news covering TCS affairs and the broader spectrum of coastal issues.

TCS representatives present congressional testimony on coastal management, conservation, and **water quality**. Recently the organization drafted a policy statement and it plans to take public positions on proposed policies affecting coastal issues.

Coastal Zone Management Act (1972)

The Coastal Zone Management Act (CZMA) of 1972 established a federal program to help states in planning and managing the development and protection of coastal areas through the creation of a Coastal Zone Management Program (CZMP). The CZMA is primarily a planning act, rather than an environmental protection or regulatory act. Under its provisions, states can receive grants from the federal government to develop and implement coastal zone programs as long as the programs meet with federal approval. State participation in the program is voluntary, and the authority is focused in state governments. In 2002, 99.9% of the national shoreline and coastal waters were managed by state CZMPs.

In the 1960s, public concern began to focus on **dredging** and filling, industrial siting, offshore oil development, and second home developments in the coastal zone. The coastal zone law was developed in the context of increased development of marine and coastal areas, need for more coordinated and consistent governmental efforts, an increase in general environmental consciousness and public **recreation** demands, and a focus on **land-use control** nationally. In 1969, a report by the Commission on Marine Sciences, Engineering, and Resources (the Stratton Commission) recommended a federal grant program to the states to help them deal with coastal zone management. The Commission found that coastal areas were of prime national interest, but development was taking place without proper consideration of environmental and resource values.

During congressional debate over coastal zone legislation, support came primarily from marine scientists and affected state government officials. The opposition emanated from development and real estate interests and industry, who were also concerned with national **land use** bills. The major difference between House and Senate versions of the legislation that passed was which department would administer the program. At the executive level there was no debate: the Office of Coastal Zone Management (now the Office of Ocean and Coastal Resource Management, or OCRM), part of the National Ocean Service of NOAA, was placed in charge of the program. But Congressional opinion varied about the administrative oversight of the Act. The House favored the **U.S. Department of the Interior** (DOI); the Senate, the **National Oceanic and Atmospheric Administration** (NOAA), part of the Department of Commerce (DOC). The Senate position was adopted in conference.

The congressional committees and executive branch agencies involved in coastal zone management also greatly varied. The Senate Commerce Committee was selected to have jurisdiction over the legislation. The House originally designated the Merchant Marine and Fisheries Committee as its legislative arm, but it was dissolved in the mid 1990s. In 2002, the current House committee is the Committee on Resources with the Subcommittee on Fisheries Conservation, Wildlife, and Oceans as its working division.

The CZMA declared that "there is a national interest in the effective management, beneficial use, protection, and development of the coastal zone." The purpose of the law is to further the "wise use of land and **water resources** for the coastal zone giving full consideration to ecological, cultural, historic and aesthetic values as well as to needs for economic development." The program is primarily a grant program, and the original 1972 Act authorized the spending of $186 million through 1977.

Under CZMA, the Secretary of Commerce was authorized to make grants to the states with coastal areas, including the **Great Lakes**, to help them develop the coastal zone management programs required by federal standards. The grants would pay for up to two-thirds of a state's program and could be received for no more than three years. In addition to these planning grants, the federal government could also make grants to the states for administering approved coastal zone plans. Again, the grants could not exceed two-thirds of the cost of the state program. With federal approval, the states could forward federal grant money to local governments or regional entities to carry out the act.

The federal government also has oversight responsibilities, to make sure that the states are following the approved plan and administering it properly. The key components of a state plan are to: (1) identify the boundaries of the coastal zone; (2) define the permissible uses in the coastal zone that have a significant effect; (3) inventory and designate areas of particular concern; (4) develop guidelines to prioritize use in particular areas; (5) develop a process for protection of beaches and public access to them; (6) develop a process for energy facility siting; and (7) develop a process to control shoreline **erosion**. The states have discretion in these stages. For instance, some states have opted for coastal zones very close to the water, others have drawn boundaries further inland. The states determine what uses are to be allowed in coastal zones. Developments in the coastal area must demonstrate coastal dependence.

Coastal zone management plans deal primarily with private lands, though the management of federal lands and federal activities within the coastal zone is required by the consistency provision of the CZMA which requires state

approval and must be consistent with state legislation. Indeed, this was intended as a major incentive for states to participate in the process. Although federal agencies with management responsibility in coastal zones have input into the plans, this state-federal coordination proved to be a problem in the 1980s and 1990s, especially regarding offshore oil development, due to differing interpretations of the consistency section of the CZMA.

At first, states were slow to develop plans and have them approved by federal authorities. This was due primarily to the political complexity of the interests involved in the process. The first three states to have their coastal zone management plans approved were California, Oregon, and Washington, which had their final plans approved by 1978. Both California and Washington had passed state legislation on coastal zone management prior to the federal law, California by referendum in 1972 and Washington in 1971. The California program is the most ambitious and comprehensive in the country. Its 1972 act established six regional coastal commissions with permit authority and a state coastal zone agency, which coordinated the program and oversaw the development of a state coastal plan. The California legislature passed a permanent coastal zone act in 1976 based on this plan. The permanent program stemmed from local plans reviewed by the regional commissions and state agency. Any development altering density or intensity of land use requires a permit from the local government, and sensitive coastal resource areas receive additional protection. As of May 2002, of the thirty-five eligible states and territories, thirty-three had approved coastal zone plans, one (Indiana) was in the planning process, and one (Illinois) had chosen not to participate in the program.

Three major issues arose during the state planning processes. Identifying areas of crucial environmental concern was a controversy that pitted environmentalists against developers in many states. In general, developers have proved more successful than environmentalists. A second issue is general development. States that have the most advanced coastal programs, such as California, use a permit system for development within the coastal zone. Environmental concerns and cumulative effects are often considered in these permit decisions. These permit programs often lead developers to alter plans before or during the application process. Such programs have generally served to improve development in coastal zones, and to protect these areas from major abuses.

The final issue, the siting of large scale facilities, especially energy facilities, has proven to be continually controversial as states and localities seek control over siting through their coastal zone plans, while energy companies appeal to the federal government regarding the national need for such facilities. In a number of court cases, the courts ruled that the states did have the power to block energy projects that were not consistent with their approved coastal management plans. This controversy spilled over into offshore oil development in waters in the outer continental shelf (OCS), which were under federal jurisdiction. These waters were often included in state coastal zone plans, many of which sought to prevent offshore oil development. In this case, the courts found in the 1984 ruling (*Secretary of the Interior vs. California*) that such development could proceed over state objections.

Major amendments to the CZMA were passed in 1976, 1980, 1990, and 1996. In 1976, the Coastal Energy Impact Fund was created to sponsor grants and loans to state and local governments for managing the problems of energy development. Other changes included an increase in the federal funding level from two-thirds to 80% of planning and administration, an increase in planning grant eligibility from three to four years, and the addition of planning requirements for energy facilities, shoreline erosion, and beach access.

The 1980 amendments re-authorized the program through 1985 and established new grant programs for revitalizing urban waterfronts and helping coastal cities deal with the effects of energy developments. The amendments also expanded the policies and objectives of the CZMA to include the protection of **natural resources**, the encouragement of states to protect coastal resources of national significance, and the reduction of state-federal conflicts in coastal zone policy.

Amendments to the CZMA in 1990 were included in the budget reconciliation bill. Most importantly, the amendments overturned the 1984 decision of *Secretary of the Interior vs. California*, giving states an increased voice regarding federal actions off their coasts. The law, which was strongly opposed by the Departments of Defense and Interior, gives the states the power to try to block or change federal actions affecting the coastal zones if these actions are inconsistent with adopted plans. The amendments also initiated a **nonpoint source** coastal **water pollution** grant and planning program, repealed the coastal energy impact program, and reauthorized the CZMA through 1995.

In June 2001, a federal district court judge ruled that the Department of the Interior (DOI) must ensure that any oil and gas leases it grants on the outer continental shelf off the coast of California be consistent with the State of California Coastal Management Program (CCMP). The decision requires the Minerals Management Service of the DOI to provide proof that 36 federally-owned oil and gas drilling leases comply with CCMP guidelines. The case is the first to uphold state rights in federal oil leasing activities granted in the 1990 CZMA amendments.

The 1996 reauthorization of the CZMA extended the Act through September 30, 1999. However, several environmental issues—including debate over funding for nonpoint **pollution** programs and lobbying by the oil and gas industry to give the states less control over federal projects such as offshore drilling leases— have delayed its further reauthorization. The continuous **resistance** by industry to curtain the rights of states or the rights of the Federal government to restrict oil and gas exploration and expansion has been in the forefront of the battle to reauthorize the CZMA. New admendments and even new legislation have been proposed that limit states from interfering in industry decisions in certain areas or limit the Federal government in others. It is clear from this contradictory legislation, that industry wants the consistency provision to only work when it is in the industry's interests.

The 106th Congress failed to vote on CZMA amendments entitled the Coastal Management Enhancement Act of 1999, but the legislation was reintroduced as the Coastal Zone Enhancement Reauthorization of 2001 by co-sponsoring Senators Olympia Snowe (R-Maine) and John Kerry (D-Mass.). As of May 2002, it had not yet been put to a Senate vote. *See also* Environmental law; Environmental policy; International Joint Commission; Marine pollution; National lakeshore; Water pollution

Co-composting

As a form of **waste management**, **composting** is the process whereby **organic waste** matter is microbiologically degraded under **aerobic** conditions to achieve significant volume reduction while also producing a stable, usable end product. Co-composting refers to composting two or more waste types in the same vessel or process, thus providing cost and space savings. The most common type of co-composting practiced by counties and townships in the United States involves mixing sewage **sludge** and **municipal solid waste** to speed the process and increase the usefulness of the end product. The processing and ultimate use or disposal of co-composting end products are regulated by federal and state environmental agencies.

Coevolution

Species are said to "coevolve" when their respective levels of fitness depend not only on their own genetic structure and adaptations but also the development of another species as well. The **gene pool** of one species creates selection pressure for another species. Although the changes are generally reciprocal, they may also be unilateral and still be considered coevolutionary.

The process of coevolution arises from interactions that establish structure in communities. A variety of different types of interactions can occur–symbiotic, where neither member suffers, or parasitic, predatory, and competitive relationships, where one member of a species pair suffers.

Coevolution can result from mutually positive selection pressure. For example, certain plants have in an evolutionary sense created positive situations for insects by providing valuable food sources for them. In return the insects provide a means to distribute pollen that is more efficient than the distribution of pollen by wind. Unfortunately, the plant and the insect species could evolve into a position of total dependency through increased specialization, thus enhancing the risk of **extinction** if either species declines.

Coevolution can also arise from negative pressures. Prey species will continually adapt defensive or evasive systems to avoid predation. Predators respond by developing mechanisms to surmount these defenses. However, these species pairs are "familiar" with one another, and neither of the strategies is perfect. Some prey are always more vulnerable, and some predators are less efficient due to the nature of variability in natural populations. Therefore the likelihood of extinction from this association is limited.

Several factors influence the likelihood and strength of coevolved relationships. Coevolution is more likely to take place in pairs of species where high levels of co-occurrence are present. It is also common in cases where selective pressure is strong, influencing important functions such as reproduction or **mortality**. The type of relationship—be it mutualistic, predator-prey, or competitor—also influences coevolution. Species that have intimate relationships, such

as that of a specialist predator or a host-specific parasite, interact actively and thus are more likely to influence each other's selection. Species that do not directly encounter each other but interact through **competition** for resources are less likely candidates to coevolve, but the strength of the competition may influence the situation.

The result of coevolved relationships is structure in communities. Coevolution and **symbiosis** create fairly distinct relationships in communities, relationships that are mirrored in distribution, community energetics, and **resistance** to disturbances in species. Coevolution allows for recurring groupings of plant and animal communities.

Cogeneration

Cogeneration is the multiple use of energy from a single primary source. In burning **coal**, oil, **natural gas**, or **biomass**, it is possible to produce two usable forms of energy at once, such as heat and electricity. By harnessing heat or exhaust from boilers and furnaces, for example, cogeneration systems can utilize energy that is usually wasted and so operate at a higher efficiency.

The second law of thermodynamics states that in every energy conversion there is a loss of useful energy in the form of heat. It is estimated that nearly half of the energy used in the United States is wasted as heat. Energy conversion efficiencies vary in range but most systems fall below 50%: A **gasoline** internal **combustion** engine is 10–15% efficient, and a steam turbine operates at about 40% efficiency. A simple example of cogeneration would be the heater in an **automobile**, which utilizes the heat of the engine to warm the interior of the car.

Cogeneration is classified into a topping cycle or a bottoming cycle. In the topping cycle, power is generated first, then the spent heat is utilized. In the bottoming cycle, thermal energy is used first, then power is generated from the remaining heat. The basic component of a cogeneration system is the prime mover, such as an internal combustion engine or steam boiler combination, whose function is to convert chemical energy or thermal energy into mechanical energy. The other components are the generator which converts mechanical input into electrical output and a spent heat recovery system, as well as control and transmission systems. A cogeneration system utilizes the heat which the prime mover component has not converted into mechanical energy, and this can improve the efficiency of a typical gas turbine from approximately 12–30% to an overall rate of 60%.

In the United States, 40% of all electrical power is generated by burning coal, and coal-fired **power plants** lose two-thirds of their energy through the smokestack. Several large **electric utilities** have been using waste heat from their boilers for space heating in their own utility districts. This is known as district heating; zoning regulations and building locations permit this practice in New York City, New York; Detroit, Michigan; and Eugene, Oregon; among other cities. Waste heat from the generation of electricity has long been used in Europe to heat commercial and industrial buildings, and the city of Vestras, Sweden, produces all its electricity as well as all its space heating by utilizing the waste heat from industrial boilers.

In 1978, Congress passed the Public Utilities Regulatory Act, which allowed cogenerators to sell their extra power to utility companies. It has been estimated that if all waste heat generated by industry were used to cogenerate electrical power, there would be no need to construct additional power plants for the next two or three decades. The paper industry in the United States, which must produce steam for its industrial process, often uses cogeneration systems to produce electricity.

Experts maintain that half of the money consumers spend on electric bills pays not for the generation of power but for its distribution and transmission, including losses through transmission. Small, decentralized cogeneration systems that burn biomass, such as **organic waste** in agricultural areas, or **garbage** from large apartment buildings can minimize transmission losses and utilize waste heat for space heating. In Santa Barbara County, California, a hospital which operates a seven-megawatt natural gas turbine generator for its electrical power needs a cogeneration system installed to use thermal energy from the boiler to provide steam for heating and cooling. Extra steam not needed for these purposes is returned to the turbine, and excess electrical power is sold to the local utility.

A new technology for regeneration systems is **coal gasification**. Coal is heated and turned into a gas. The gas is burned to operate two turbines, one fueled by the hot gases and the other by steam generated from the burning gas. **Scrubbers** can remove 95% of the sulfur from the flue gases, and the result is a generating facility with high efficiency and low **pollution**.

Cold fusion

Nuclear fusion has long been thought to have the potential to be a cheap and virtually unlimited source of energy. However, fusion requires extremely high temperatures or pressures. Cold fusion is fusion occurring at moderate temperatures and pressures. Cold fusion could make fusion more practical.

Fusion refers to a process where atomic nuclei collide and fuse together, forming larger particles and releasing energy. The fusion of **hydrogen** nuclei inside the sun is what makes the heat that warms our planet. But outside the enormous pressure in the center of a star like the sun, nuclei are unlikely to fuse. All atomic nuclei are positively charged, and thus repel each other. Some outside force, such as high temperature or pressure, is needed to make the nuclei overcome their natural repulsion and come together. If nuclei could be forced to fuse at low temperatures in a practical device, it would be possible to produce large amounts of energy at a reasonable cost.

One of the fathers of modern physics, Ernest Rutherford, investigated the possibility of cold fusion using deuterium (an **isotope** of hydrogen) atoms in 1934. However, he could find no viable method for achieving fusion at low temperatures.

Meanwhile, experiments with high temperature fusion proceeded. In the 1950s, scientists experimented with magnetic bottles as fusion devices. Theoretically, gas could be heated to such high temperatures inside the magnetic bottle that hydrogen nuclei would fuse, as they do in the sun. A physics laboratory at Princeton University in Princeton, New Jersey, built a magnetic containment device, a massive machine called the Tokamak. It did produce some energy from fusion, but using the Tokamak or anything like it as a power source is not practical, since it requires more energy to make fusion happen than it produce from the fusion reaction. Scientists continued to research various methods of fusion. If energy could be produced from an abundant material like hydrogen or deuterium, the earth would have an almost limitless, new, clean power source, the thinking went. The potential benefits were enormous.

Since cold fusion would operate at low temperatures and pressures, it would not require the expensive and complex equipment needed for high temperature fusion. Cold fusion research was filled with disappointments and dead ends, but scientists continued to experiment. Cold fusion has been called the "Holy Grail" of physics, because it seems virtually unattainable.

In 1989, Stanley Pons and Martin Fleischmann, two electrochemists working at the University of Utah, stunned the world with their announcement that they had performed cold fusion in a plastic dishpan using a small laboratory device. Pons was a prolific researcher in electrochemistry, and Fleischmann was an esteemed member of the British Royal Society and a professor at the University of Southampton in England. The two had collaborated for years, and in the mid-1980s Fleischmann had become a visiting professor at Utah. Their device electrically charged a cathode made of palladium, a metal that contains high concentrations of hydrogen isotopes. Apparently aiming to protect their patent rights to this revolutionary device, Pons and Fleischmann made their first cold fusion claim directly to the popular press, bypassing the scientific community by not submitting their discovery first to a professional journal where it would be reviewed by other scientists.

Pons and Fleischmann were temporarily heroes, appearing before Congress to help the University of Utah secure funding for cold fusion research. Meanwhile, many experts in fusion research and other physicists were less easily convinced. If the palladium cathode was actually fusing hydrogen isotopes, it would have emitted dangerous levels of radiation. The very fact that the clearly healthy scientists had been photographed beaming next to their cold fusion machine alerted knowledgeable people that the device could not be working as Pons and Fleischmann claimed. Within weeks it became clear that Pons and Fleischmann had made some elementary mistakes. It was thought that the energy increase they detected came from pockets of heat in the fluid, caused by the liquid not being stirred enough. Although a number of scientists around the world continued to research it, within ten years of the Utah experiments the discovery of cold fusion seemed to be discredited.

Pons and Fleischmann suffered a serious loss of reputation after the cold fusion debacle, ultimately losing a libel suit they brought against an Italian newspaper that had labeled them frauds. The Japanese government continued to support cold fusion research through much of the 1990s, but finally abandoned all its financial support in 1998. It seemed that only a few hundred scientists worldwide were working on cold fusion in 2001, judging from attendance at a semi-annual conference on the topic. In 2002, a researcher at the Oak Ridge National Laboratory in **Oak Ridge, Tennessee**, claimed to have detected something that might have been cold fusion using a process called acoustic cavitation. This produced high pressure in a liquid by means of sound waves. But with the stark example of Pons and

Fleischmann, any new claim to cold fusion will have to be carefully substantiated by a number of scientists before it can overcome existing skepticism.

Coliform bacteria

Coliform bacteria live in the nutrient-rich **environment** of animal intestines. Many **species** fall into this group, but the most common species in mammals is ***Escherichia coli***, usually abbreviated *E. coli*. A typical human can easily have several trillion of these tiny individual bacterial cells inhabiting his or her digestive tract. On a purely numerical basis, a human may have more bacterial than mammalian cells in his or her body. Each person is actually a community or **ecosystem** of diverse species living in a state of cooperation, competition, or coexistence.

The bacterial **flora** of one's gut provides many benefits. They help break down and absorb food, they synthesize and secrete vitamins such as B_{12} and K on which mammals depend, and they displace or help keep under control pathogens that are ingested along with food and liquids. When the pathogens gain control, disagreeable or even potentially lethal diseases can result. A wide variety of diarrheas, dysenteries, and other gastrointestinal diseases afflict people who have inadequate **sanitation**. Many tourists suffer traveler's diseases known by names such as Montezuma's Revenge, La Tourista, or Cairo Crud when they come into contact with improperly sanitized water or food. Some of these diseases, such as **cholera** or food **poisoning** caused by *Salmonella*, *Shigella*, or *Lysteria* species, can be fatal.

Because identifying specific pathogens in water or food is difficult, time-consuming, and expensive, public health officials usually test for coliform organisms in general. The presence of any of these species, whether pathogenic or not, indicates that fecal contamination has occurred and that pathogens are likely present.

Colorado River

One of the major rivers of the western United States, the Colorado River flows for some 1,500 mi (2,415 km) from Colorado to northwestern Mexico. Dropping over 2 mi (3.2 km) in elevation over its course, the Colorado emptied into the Gulf of California until human management reduced its water flow. Over millions of years the swift waters of the Colorado have carved some of the world's deepest and most impressive gorges, including the Grand Canyon.

The Colorado River basin supports an unusual **ecosystem**. Isolated from other **drainage** systems, the Colorado has produced a unique assemblage of fishes. Of the 32 **species** of native fishes found in the Colorado drainage, 21–66%, are endemic species—species that arose in the area and are found nowhere else.

Major projects carried out since the 1920s have profoundly altered the Colorado. When seven western states signed the Colorado River Compact in 1922, the Colorado became the first basin in which "multiple use" of water was initiated. Today the river is used to provide hydroelectric power, **irrigation**, drinking water, and **recreation**; over 20 **dams** have been erected along its length. The river, in fact, no longer drains into the Gulf of Colorado—it simply disappears near the Mexican towns of Tijuana and Mexicali. Hundreds of square miles of land have been submerged by the formation of reservoirs, and the temperature and clarity of the river's water have been profoundly changed by the action of the dams.

Alteration of the Colorado's **habitat** has threatened many of its fragile fishes, and a number are now listed as **endangered species**. The Colorado squawfish serves as an example of how river development can affect native **wildlife**. With the reservoirs formed by the impoundments on the Colorado River also came the introduction of game fishes in the 1940s. One particular species, the Channel catfish, became a prey item for the native squawfish, and many squawfish were found dead, having suffocated due to catfish lodged in their throats with their spines stiffly locked in place. Other portions of the squawfish population have succumbed to diseases introduced by these non-native fishes.

Major projects along the Colorado include the Hoover Dam and its **reservoir**, Lake Mead, as well as the controversial **Glen Canyon Dam** at the Arizona-Utah border, which has a reservoir extending into Utah for over 100 mi (161 km).

Combined sewer overflows

In many older coastal cities, especially in the northeastern United States, storm sewers in the street that collect stormwater **runoff** from rainfall are connected to municipal **sewage treatment** plants that process household sewage and industrial **wastewater**. Under normal, relatively dry conditions runoff and municipal waste go to a sewage treatment plant where they are treated. However, when it rains, in some cases less than an inch, the capacity of a sewage treatment plant can be exceeded; the system is overloaded. The mixed urban stormwater runoff and raw municipal sewage is released to nearby creeks, rivers, bays, estuaries or other coastal waters, completely untreated. This is a combined sewer overflow (CSO) event.

Combined sewer overflow events are not rare. In Boston Harbor, for example, there are 88 pipes or outfalls that **discharge** combined stormwater runoff and sewage. It has been estimated that CSO events occur approximately 60 times per year, discharging billions of gallons of untreated runoff and wastewater to Boston Harbor.

Materials released during these CSO events can result in serious **water quality** problems that can be detrimental to both humans and **wildlife**. Toxic **chemicals** from households and industries are released during CSO events. In addition, toxic chemicals found in rainwater runoff, such as oil and antifreeze that have dripped onto roads from cars, will wash into coastal waters during these events.

Harmful bacteria and pathogens in the water are another major problem that can result after a CSO event. Some of these bacteria (coliform), live naturally in the intestinal tracts of humans and other warm blooded animals. After heavy rainfalls, scientists have measured increased levels of **coliform bacteria** in coastal waters near CSO outfalls. These bacteria, which indicate that there are other bacteria and pathogens that can make people sick if they swim in the water or eat contaminated shellfish, come from both animal and human wastes washed in from the streets. The bacteria are not removed or killed because the waters have not been treated in a sewage treatment plant. Because levels of these indicator bacteria are often high after CSO events, many productive shellfish beds are closed to protect human health. This can be a serious economic hardship to the fishing industry.

Combined sewer overflow events also result in increased quantities of trash and **floatable debris** entering coastal waters. When people litter, the trash is washed into storm sewers with rainwater. Since sewage treatment plants cannot handle the volume of water during these rainfall events, this trash is discharged along with the stormwater and sewage directly into open waters. This floatable debris is unsightly, and can be dangerous to marine animals and birds, which eat it and choke or become entangled within it. This often results in death.

Raw sewage, animal wastes, and runoff from lawns and other fertilized areas contain very high levels of **nitrogen** and **phosphorus**, which are nutrients used by marine and aquatic plants for growth. Therefore, CSO events are major contributors of extra nutrients and organic matter to nearshore waters. These nutrients act as fertilizers for many marine and aquatic algae and plants, promoting extreme growth called blooms. When they eventually die, the bacteria decomposing the plants and algae use up vast quantities of oxygen. This results in a condition known as hypoxia or low **dissolved oxygen** (DO). If DO levels are too low, marine animals will not have enough oxygen to survive and they will either die or move out of the area. Hypoxia has been the cause of some major **fish kills**, and can result in permanent changes in the ecological community if it is persistent.

There are a number of options available to reduce the frequency and impacts of CSO events. Upgrading sewage treatment plants to handle greater flow or constructing new facilities are two of the best, although most costly options. Another possibility is to separate storm sewers and municipal sewage treatment plants. While this would not prevent discharges of stormwater runoff during rainfall events, untreated household and industrial wastewater (i.e., raw sewage) would not be released. In addition, the resulting stormwater could be minimally treated by screening out trash and disinfecting it to kill bacteria. Use of **wetlands** to filter this stormwater has also been considered as an effective alternative and is currently being used in some areas. Another option is to build large storage facilities (often underground) to hold materials that would normally be discharged during CSO events. When dry conditions return, the combined runoff and wastewater are pumped to a nearby sewage treatment plant where they are properly treated. This option is being used in several areas, including some locations in New York City. At a minimum, screening of CSO discharges would reduce the quantity of floatable debris in nearshore waters, even if it did not solve all of the other problems associated with CSOs. Of course **water conservation** is another control that reduces that volume of water treated by sewage treatment plants, and therefore the volume that would be discharged during a CSO event.

Combustion

The process of burning fuels. Traditionally **biomass** was used as fuel, but now **fossil fuels** are the major source of energy for human activities. Combustion is essentially an oxidation process that yields heat and light. Most fuels are **carbon** and **hydrogen** which use oxygen in the air as an oxidant. More exotic fuels are used in some combustion processes, particularly in rockets where metals such as **aluminum** or beryllium or hydrazine (a **nitrogen** containing compound) are well known as effective fuels. As rockets operate beyond the **atmosphere** they carry their own oxidants, which may also be quite exotic.

Combustion involves a mixture of fuel and air, which is thermodynamically unstable. The fuel is then converted to stable products, usually water and **carbon dioxide**, with the release of a large amount of energy as heat. At normal temperatures fuels such as **coal** and oil are quite stable and have to be ignited by raising the temperature. Combustion is said to be spontaneous when the ignition appears to take place without obvious reasons. Large piles of organic material, such as hay, can undergo slow oxidation, perhaps biologically mediated, and increase in temperature. If the amount of material is very large and the heat cannot escape, the whole pile can suddenly burst into flame. Will-o'-the-wisps or jack-o'-lanterns (known scientifically as *ignis fatuus*) are sometimes observed over swamps where **methane** is likely to be produced. The reason these small pockets of gas ignite is not certain, but it has been suggested that small traces of gases such as phosphine that react rapidly with air could ignite the methane.

Typical solid fuels like coal and wood begin to burn with a bright turbulent flame. This forms as volatile materials are driven off and ignited. These vapors burn so rapidly that oxygen can be depleted, creating a smoky flame. After a time the volatile substances in the fuel are depleted. At this point a glowing coal is evident and combustion takes place without a significant flame. Combustion on the surface of the glowing coal is controlled by the diffusion of oxygen towards the hot surface. If the piece of fuel is too small, such as a spark from a fire, it is likely to lose temperature rapidly and combustion will stop. By contrast a bed of coals can maintain combustion because of heat storage and the exchange of radiative heat between the pieces. The most intense combustion takes place between the crevices of a bed of coal. In these regions oxygen may be in limited supply which leads to the production of **carbon monoxide**. This is subsequently oxidized to carbon at the surface of the bed of coals with a faint blue flame. The production of toxic carbon monoxide from indoor fires can occasionally represent a hazard if subsequent oxidation to carbon dioxide is not complete.

Liquid fuels usually need to be evaporated before they burn effectively. This means that it is possible to see liquid combustion and gaseous combustion as similar processes. Combustion can readily be initiated with a flame or spark. Simply heating a fuel-air mixture can cause it to ignite, but temperatures have to be high before reactions occur. A much better way is to initiate combustion with a small number of molecular fragments of radicals. These can initiate chain reactions at much lower temperatures than molecular reactions. In a propane-air flame at about 2000° K, hydrogen and oxygen atoms and hydroxyl radicals account for about 0.3% of a gas mixture. It is these radicals that support combustion. They react with molecules and split them up into more radicals. These radicals can rapidly enter into the exothermic (heat releasing) oxidative processes that lie at the heart of combustion. The reactions also give rise to further radicals that support continued combustion. Under some situations the radicals reaction branch, such that the reaction of each radical produces two new radicals. These can enter further reactions, producing yet further increases in the number of reactions and very soon the system explodes. However the production of radicals can be terminated in a number of ways such as contact with a solid surface. In some systems, such as the internal combustion engine, an explosion is desired, but in others, such as a gas cooker flame, maintaining a stable combustion process is desirable.

In terms of **air pollution** the reaction of oxygen and nitrogen atoms with molecules in air leads to the formation of the pollutant nitric oxide through a set of reactions known as the Zeldovich cycle. It is this process that makes combustion such an important contributor of **nitrogen oxides** to the atmosphere.

Cometabolism

The partial breakdown of a (usually) synthetic compound by microbiological action. Synthetic **chemicals** are widely used in industry, agriculture, and in the home; many resist complete enzymatic degradation and become persistent environmental pollutants. In cometabolism, the exotic molecule is only partly modified by **decomposers** (bacteria or **fungi**), since they are unable to utilize it either as a source of energy, as a source of **nutrient** elements, or because it is toxic. Cometabolism probably accounts for long-term changes in DDT, dieldrin, and related chlorinated hydrocarbon insecticides in the **soil**. The products of this partial transformation,

like the original exotic chemical, usually accumulate in the **environment**.

Commensalism

A type of symbiotic relationship. Many organisms depend on intimate physical relationship with organisms of other **species**, a relationship called **symbiosis**. The larger organism is called the host and the smaller organism, the symbiote. The symbiote always derives some benefit from the relationship. In a commensal relationship, the host organism is neither harmed nor benefitted. The relationship that exists between the clown fish living among the tentacles of sea anemones is one example of commensalism. The host sea anemones can exist without their symbiotes, but the fish cannot exist as successfully without the protective cover of the anemone's stinging tentacles.

Commercial fishing

Because fish have long been considered an important source of food, the fisheries were the first renewable resource to receive public attention in the United States. The National Marine Fisheries Service (NMFS) has existed as such since 1970, but the original Office of Commissioner of Fish and Fisheries was created over 100 years ago, signed into law in 1871 by President Ulysses S. Grant. This office was charged with the study of "the decrease of the food fishes of the seacoasts and lakes of the United States, and to suggest remedial measures." From the beginning, the federal fishery agency has been granted broad powers to study aquatic resources ranging from coastal shallow waters to offshore deepwater habitats.

Worldwide, humans get an average of 16% of their dietary animal protein from fish and shellfish. With human populations ever increasing, the demand for and marketing of seafood has steadily increased, rising over the last half of the twentieth century to a peak in 1994 of about 100 million tons (91 billion kg) per year. The current annual marine fish catch has fallen slightly to around 70 million tons (64 billion kg). The per capita world fish catch has been steadily declining since 1970 as human **population growth** outdistances fish harvests. Scientists have projected that, by 2020, the per capita consumption of ocean fish will be half of what it was in 1988.

To meet the demand for fish, the commercial fishing industry has expanded as well. There are currently about 13 million commercial fishermen in the world. About half of the fish are caught by the vast majority of fishers who use traditional methods. The remainder is harvested by industrial fishing crews, manning about 37,000 vessels that deploy highly innovative methods ranging from enormous nets to sonar and spotting planes. As a result, wild fish populations have been decimated.

In recent decades, the size of the industrial fishing fleet grew at twice the rate of the worldwide catch. The expansion in fishing may be coming to an end, however, as environmental, biological, and economic problems beset the fishing industry. As fish harvests decline, the numbers of jobs also decline. Governments have attempted to prop up the failing fisheries industry: in 1994, fishers worldwide spent $124 billion to catch fish valued at $70 billion, and the shortfall was covered by government subsidies. In recent decades, fishery imports have been one of the top five sources of the United States' trade deficit.

The commercial fisheries industry has contributed to its own problems by **overfishing** certain **species** to the point where those species' populations are too low to reproduce at a rate sufficient to replace the portion of their numbers lost to harvesting. Cod and haddock in the Atlantic Ocean, red snapper in the Gulf of Mexico, and **salmon** and tuna in the Pacific Ocean have all fallen victim to overfishing. The case of the Peruvian anchovy represents a specific example of how several factors may work together to contribute to species decline. Fishing for anchovies began off the coast of Peru in the early 1950s, and, by the late 1960s, as their fishing fleet had grown exponentially, the catch of Peruvian anchovies made up about 20% of the world's annual commercial fish harvest. The Peruvian fishermen were already overfishing the anchovies when meteorological conditions contributed to the problem: in 1972, a strong **El Niño** struck. This phenomenon is a natural but unpredictable warming of the normally cool waters that flow along Peru's coast. The entire food web of the region was altered as a result, and the Peruvian anchovy population plummeted, leading to the demise of Peru's anchovy fishing industry. Peru has made some economic recovery since then by harvesting other species.

Many of the world's major fishing areas have already been fished beyond their natural limits. Different approaches to the problem of overfishing are under consideration to help prevent the collapse of the world's fisheries. **Georges Bank**, once one of the most fertile fishing grounds in the North Atlantic, is now closed and is considered commercially extinct. This area underwent strict controls for scallop fishing in 1996, which proved to be a viable remedy for that species in that locale. The scallop population recovered within five years, reaching levels in excess of the original population, and parts of the bay could be re-opened for scallop fishing. But other species in Georges Bank continue to decline. Rapid and direct replenishment is not possible for slow-growing species that take years to reach maturity. For example, the black sea bass (*Stereolepis gigas*), has a life span

comparable to that of humans and adults typically grow to 500 lb (227 kg). The success of a 1982 ban on fishing the black sea bass off the coast of California became evident early this century when significant numbers of these young fish, already weighing as much as 200 lb (91 kg), appeared off the shores of Santa Barbara. Yet, full replenishment of the population remains years away.

Environmental problems also **plague** commercial fishing. Near-shore **pollution** has altered ecosystems, taking a heavy toll on all populations of fish and shellfish, not only those valued commercially. The collective actions of commercial fishermen also create some major environmental problems. The world's commercial fishermen annually catch and then discard about 20 billion lb (9 billion kg) of non-target species of sea life. In addition to fish and shellfish, each year about one million seabirds are caught and killed in fishermen's nets. On average more than 6,000 **seals and sea lions**, about 20,000 **dolphins** and other aquatic mammals, and thousands of **sea turtles** meet the same fate. It is estimated that the amount of fish discarded annually is about 25% of the reported catch, or about 20 million metric tons per year. Ecologically, two major problems arise from this massive disposal of organisms. One is the disruption of predator-prey ratios, and the other is the addition of a tremendous overload of **organic waste** to be dealt with in this **ecosystem**.

In 2001, a $1.6 billion gas pipeline that was proposed to be routed through neighboring waters from Nova Scotia to New Jersey, to be implemented as early as 2005, posed a new environmental threat to the Georges Bank area. Environmentalists, meanwhile, have lobbied the United States government to establish a marine **habitat** protection designation similar to **wilderness** areas and natural parks on land, to provide for the preservation of reefs, marine life, and underwater vegetation. In 2001, less than 1% of **water resources** worldwide had the protection of formal legislation to prevent exploitation.

Habitat destruction is serious environmental concern. Fish and other aquatic **wildlife** rely on the existence of high quality habitat for their survival, and loss of habitat is one of the most pressing environmental threats to shorelines, **wetlands**, and other aquatic habitats. Approaches to the protection of **essential fish habitat** include efforts to strengthen and vigorously enforce the **Clean Water Act** and other protective legislation for aquatic habitats, to develop and implement restoration plans for target regions, to make improved policy decisions based on technical knowledge about shoreline habitats, and to better educate the public on the importance of protecting and restoring habitat. A relatively new approach to habitat recovery is the habitat **conservation** plan (HCP), in which a multi-species ecosystem approach to habitat management is preferred over a reactive species-by-species plan. Strategies for fish recovery are complex, and, instead of numbers of fish of a given species, the HCP uses quality of habitat to measure the success of restoration and conservation efforts. Long-term situations such as the restoration of black sea bass serve to re-emphasize the importance of resisting the temptation to manage overfishing of single species while failing to address the survival of the ecosystem as a whole.

The Magnuson-Stevens Fishery Conservation and Management Act was passed in 1976 to regulate fisheries resources and fishing activities in Federal waters, those waters extending to the 200-mi (322-km) limit. The act recognizes that commercial fishing contributes to the food supply and is a major source of employment, contributing significantly to the economy of the Nation. However, it also recognizes that overfishing and habitat loss has led to the decline of certain species of fish to the point where their survival is threatened, resulting in a diminished capacity to support existing fishing levels. Further, international fishery agreements have not been effective in ending or preventing overfishing. Fishery resources are limited but renewable and can be conserved and maintained to continue to provide good yields. Also, the act supports the development of underused fisheries, such as bottom-dwelling fish near Alaska.

Another resource to sustain increases in seafood consumption is **aquaculture**, where commercial food-fish species are grown on fish farms. It is estimated that the amount of farm-raised fish has doubled in the past decade and that about 20% of the fish consumed worldwide is raised in captivity.

In the United States, as well as other nations, the commercial fisheries industry faces potential collapse. Severe restrictions and tight controls imposed by the international community may be the only means of salvaging even a portion of this valuable industry. It will be necessary for partnerships to be forged between scientists, fisherman, and the regulatory community to develop and implement measures toward maintaining a sustainable fishery.

Commission for Environmental Cooperation

The Commission for Environmental Cooperation (CEC) is a trilateral international commission established by Canada, Mexico, and the United States in 1994 to address transboundary environmental concerns in North America. The original impetus behind the CEC was the perception of inadequacies in the environmental provisions of the **North American Free Trade Agreement** (NAFTA). A supplementary treaty, the North American Agreement for Environmental Cooperation (NAAEC) was negotiated to remedy these inadequacies, and it is from the NAAEC that the CEC derives its formal mandate.

The general goals set forth by the NAAEC are to protect, conserve, and improve the **environment** for the benefit of present and **future generations**. More specifically, the three NAFTA signatories agreed to a core set of actions and principles with regard to environmental concerns related to trade policy. These actions and principles include regular reporting on the state of the environment, effective and consistent enforcement of **environmental law**, facilitation of access to environmental information, the ongoing improvement of environmental laws and regulations, and promotion of the use of tax incentives and various other economic instruments to achieve environmental goals.

The CEC is to function as a forum for the NAFTA partners to identify and articulate mutual interests and priorities, and to develop strategies for the pursuit or implementation of these interests and priorities. The NAAEC further specifies the following priorities: identification of appropriate limits for specific pollutants; the protection of endangered and threatened **species**; the protection and **conservation** of wild **flora** and **fauna** and their **habitat**; the development of new approaches to environmental compliance and enforcement; strategies for addressing environmental issues that have impacts across international borders; the support of training and education in the environmental field; and promotion of greater public awareness of North American environmental issues. Central to the CEC's mission is the facilitation of dialogue among the NAFTA partners in order to prevent and solve trade and environmental disputes.

The governing body of the CEC is a Council of Ministers consisting of the environment ministers (or equivalent) from each country. The executive arm of the Commission is a Secretariat located in Montreal, consisting of a staff of about 30 members and headed by an Executive Director. The staff is drawn from all three countries and provides technical and administrative support to the Council of Ministers and to committees and groups established by the Council.

Technical and scientific advice is also provided to the Council of Ministers by a Joint Public Advisory Committee consisting of five members from each country appointed by the respective governments. This Committee may, on its own initiative, advise the Council on any matter within the scope of the NAAEC, including the annual program and budget. As a reflection of the CEC's professed commitment to participation by citizens throughout North America, the Committee is intended to represent a wide cross-section of knowledgeable citizens committed to environmental concerns who are willing to volunteer their time in the public interest. The CEC also accepts direct input from any citizen or non-governmental organization who believes that a NAFTA partner is failing to enforce effectively an existing environmental law.

The NAAEC also contains provisions for dispute resolution in cases in which a NAFTA signatory alleges that another NAFTA partner has persistently failed to enforce an existing environmental law, causing specific environmental damage or trade disadvantages to the claimant. These provisions may be invoked when a lack of effective enforcement materially affects goods or services being traded between the NAFTA countries. If the dispute is not resolved through bilateral consultation, the complaining party may then request a special session of the CEC's Council of Ministers. If the Council is likewise unable to resolve the dispute, provisions exist for choosing an Arbitral Panel. Failure to implement the recommendations of the Arbitral Panel subjects the offending party to a monetary enforcement assessment. Failure to pay this assessment may lead to suspension of free trade benefits.

The Council is also instructed to develop recommendations on access to courts (and rights and remedies before

courts and administrative agencies) for persons in one country's territory who have suffered or are likely to suffer damage or injury caused by **pollution** originating in the territory of one of the other countries. In 2002, the Council published a five year study which stated that 3.4 million tonnes of **toxins** were produced in North America.

The CEC has been subject to some of the same criticisms leveled at the environmental provisions of NAFTA, particularly that it serves as a kind of environmental windowdressing for a trade agreement that is generally harmful to the environment. The CEC's mandate for conflict resolution is primarily oriented towards consistent enforcement of existing environmental law in the three countries. This law is by no means uniform. By upholding the principles of free trade, and providing penalties for infringements of free trade, NAFTA establishes an environment in which private companies have an economic incentive, other considerations being equal, to locate production where environmental laws are weakest and the costs of compliance are therefore lowest. Countries with stricter environmental regulations face penalties for attempting to protect domestic industries from such comparative disadvantages.

Barry Commoner (1917 –)

American biologist, environmental scientist, author, and social activist

Born to Russian immigrant parents, Commoner earned a doctorate in biology from Harvard in 1941. As a biologist, he is known for his work with free radicals—chemicals like **chlorofluorocarbons**, which are suspected culprits in **ozone layer depletion**. Commoner led a fairly academic life at first, with research posts at various universities, but rose to some prominence in the late 1950s, when he and others protested atmospheric testing of **nuclear weapons**. He earned a national reputation in the 1960s with books, articles, and speeches on a wide range of environmental concerns, including **pollution**, **alternative energy sources**, and population. His latest book, *Making Peace with the Planet*, was published in 1990. Commoner's other works include *Science and Survival* (1967), *The Closing Circle* (1971), *Energy and Human Welfare* (1975), *The Poverty of Power* (1976), and *The Politics of Energy* (1979).

Barry Commoner speakingto a group of protesters gathered outside a New Jersey hotel where Exxon stockholders met in 1989. (Corbis-Bettmann. Reproduced by permission.)

Commoner believes that post-World War II industrial methods, with their reliance on nonrenewable **fossil fuels**

are the root cause of modern environmental pollution. When combined with a myopic view of the bottom line, he states, the devastation is complete: "At present, economic considerations—in particular, the private desire for maximizing short-term profits—govern the choice of productive technology, which in turn determines its environmental impact, generally for the worse." The petrochemicals industry receives the largest share of Commoner's criticism. He refers to "the **petrochemical** industry's toxic invasion of the biosphere" and states flatly that "the petrochemical industry is inherently inimical to environmental quality."

Almost as distressing as environmental pollution is our inability to clean it up. Commoner rejects attempts at environmental regulation as pointless. Far better, he says, to not produce the toxin in the first place. "When a pollutant is attacked at the point of origin—in the production process that generates it—the pollutant can be eliminated; once it is produced, it is too late. This is the simple but powerful lesson of the two decades of intense but largely futile effort to improve the quality of the environment."

Commoner offers radical, sweeping solutions for social and ecological ills. The most urgent of these is a **renewable energy** source, primarily photovoltaic cells powered by **solar energy**. These would not only decentralize **electric utilities** (another target of Commoner's), but would use sunlight to fuel almost any energy need, including smaller, lighter, battery-powered cars. To ease the transition from fossil fuels to solar power, he proposes **methane**, **cogeneration** (which produces electricity from waste heat), and an organic agriculture system that would "produce enough **ethanol** to replace about 20 percent of the national demand for **gasoline** without reducing the overall supply of food or significantly affecting its price."

Commoner makes few compromises, and his environmental zeal has made him a crusader for social causes as well. Eliminating **Third World** debt, he argues, would improve life in impoverished countries and end the spiral of economic desperation that drives countries to overpopulation. "This [debt forgiveness] should be regarded not as a magnanimous gesture but as partial reparations for the damage inflicted...by the former colonial empires...[T]he cause of poverty is the grossly unequal distribution of the world's wealth...we must redistribute that wealth, among nations and within them."

In 1980, Commoner made a bid for the presidency on the Citizen's Party ticket, a short-lived political attempt to combine environmental and Socialist agendas. Since 1981 he has been the director of the Center for the Biology of Natural Systems at Queens College in New York City.

Communicable diseases

A communicable disease is any disease that can be transmitted from one organism to another. Agents that cause communicable diseases, called pathogens, are easily spread by direct or indirect contact. These pathogens include viruses, bacteria, **fungi**, and **parasites**. Some pathogens make **toxins** that harm the body's organs. Others actually destroy cells. Some can impair the body's natural immune system, and opportunistic organisms set up secondary infections that cause serious illness or death. Once the pathogens have multiplied inside the body, signs of illness may or may not appear. The human body is adept at destroying most pathogens, but the pathogens may still multiply and spread.

The pathogens responsible for some communicable diseases have been known since the mid-1800s, although they have existed for a much longer period of time. European explorers brought highly contagious diseases such as smallpox, measles, typhus and scarlet fever to the New World, to which Native Americans had never been exposed. These new diseases killed 50–90% of the native population. Native populations in many areas of the Caribbean were totally eliminated.

In some areas of the world, **contaminated soil** or water incubate the pathogens of communicable diseases, and contact with those agents will cause diseases to spread. In the 1800s, when Robert Koch discovered the **anthrax** bacillus (*Bacillus anthracis*), **cholera** bacillus (*Vibrio cholerae*), and tubercle bacillus (*Mycobacterium tuberculosis*), his work ushered in a new era of public **sanitation** by showing how water-borne epidemics, such as cholera and typhoid, could be controlled by water **filtration**.

Malaria, another communicable disease, was responsible for the decline of many ancient civilizations; for centuries, it devitalized vast populations. With the discoveries in the late 1800s of protozoan malarial parasites in human blood, and the discovery of its carrier, the *Anopheles* mosquito, malaria could be combatted by systematic destruction of the mosquitos and their breeding grounds, by the use of

barriers between mosquitos and humans such as window screens and mosquito netting, and by drug therapy to kill the parasites in the human host.

Discoveries of the causes of epidemics and transmissible diseases led to the expansion of the fields of sanitation and public health. Draining of marshes, control of the water supply, widespread vaccinations, and quarantine measures improved human health. But, despite the development of advanced detection techniques and control measures to fight pathogens and their spread, communicable diseases still take their toll on human populations. For example, until the 1980s tuberculosis had been declining in the United States due in large part to the availability of effective antibiotic therapy. However, since 1985, the number of tuberculosis cases has risen steadily due to such factors as the emergence of drug-resistant strains of the tubercle bacillus, the increasing incidence of HIV infection which lowers human **resistance** to many diseases, poverty, and immigration.

Epidemiologists track communicable diseases throughout the world, and their work has helped to eradicate smallpox, one of the world's most deadly communicable diseases. A successful global vaccination campaign wiped out smallpox in the 1980s, and today, the **virus** exists only in tightly-controlled laboratories in Moscow and in Atlanta at the **Centers for Disease Control and Prevention**. Scientists are currently debating whether to destroy the viruses or preserve them for study.

Communicable diseases continue to be a major public health problem in developing countries. In the small West African nation of Guinea-Bissau, a cholera epidemic hit in 1990. Epidemiologists traced its outbreak to contaminated shellfish and managed to control the epidemic, but not before it claimed hundreds of lives in that country. Some victims had eaten the contaminated shellfish, others were infected by washing the bodies of cholera victims and then preparing funeral feasts without properly washing their hands. Proper disposal of victims' bodies, coupled with a campaign to encourage proper hygiene, helped stop the epidemic from spreading.

Communicable diseases can be prevented either by eliminating the pathogenic organism from the **environment** (as by killing pathogens or parasites existing in a water supply) or by placing a barrier in the path of its transmission from one organism to another (as by vaccination or by isolating individuals already infected). But identifying and isolating the causal agent and developing weapons to fight it is time consuming, and, as with the **AIDS** virus, thousands of people continue to become infected and many die because educational warnings about ways to avoid infection frequently go unheeded.

AIDS is caused by the human immunodeficiency virus (HIV). Spread by contact with bodily fluids of an HIV-infected person, the virus weakens and eventually destroys the body's immune system. Researchers think the virus originated in monkeys and was first transmitted to humans about 40 years ago. African **chimpanzees** can be infected with HIV, but don't develop AIDS. This suggests questions that are so far unanswered: Was there a genetic change in the virus, or was there simply more contact between monkeys and people as human populations encroached on their **habitat**?

Some scientists think the AIDS pandemic is just the tip of the iceberg. They worry that new diseases, deadlier than AIDS, will emerge. Virologists point out that viruses, like human populations, constantly change. Rapidly increasing human populations provide fertile breeding grounds for **microbes**, including viruses and bacteria. Pathogens can literally travel the globe in a matter of hours.

For example, the completion in 1990 of a major road through the Amazon **rain forest** in Brazil led to outbreaks of malaria in the region. In 1985, used tires imported to Texas from eastern Asia transported larvae of the Asian tiger mosquito, a dangerous carrier of serious tropical communicable diseases. **Deforestation** and agricultural changes can unleash epidemics of communicable diseases. Outbreaks of Rift Valley fever followed the construction of the **Aswan High Dam**, most likely because breeding grounds were created for mosquitoes which spread the disease. In Brazil, the introduction of cacao farming coincided with epidemics of Oropouche fever, a disease linked to a biting insect that thrives on discarded cacao hulls.

Continued rapid **transportation** of humans around the world is likely to accelerate the movement of communicable diseases. Poverty, lack of adequate sanitation and nutrition, and the crowding of people into megacities in the developing countries of the world only exacerbate the situation. The need for study and control of these disease is likely to grow in the future.

Community ecology

In biological **ecology**, the concept of community has been defined in various ways, each definition offering particular advantages and creating its own set of problems. As the

authors of one article in a 1987 British Ecological Society symposium on community ecology noted, "Community ecology may be unique amongst the branches of science in lacking a consensus definition of the entity with which it is principally concerned." Daniel Botkin provides a summary of the major alternatives: an ecological community is "either (1) a set of interacting populations of different **species** found in an area, meaning that the community is the living part of an **ecosystem**; or (2) all of the species found in a local area, whether or not they actually interact; or (3) all of the species of the same kind found in a local area, as in a 'plant community' or 'animal community'." Peter Taylor describes an ecological community as consisting "of the populations of different species co-inhabiting a site—a lake, the leaf litter layer in a forest, a dung pat, and so on."

A definition of community is significant because so many different parts of the **environment** are investigated under that rubric in ecology: animal, plant, insect, primate, forest, even herbaceous plant communities. Often what is described is a component of a community rather than a *whole* community made up of many different species of plants and animals. Such a whole assemblage in community ecology has no scale, but it does denote a certain level of organization and is different from components of a community, guilds, or taxons.

Community ecology thus focuses on the living part of ecosystems, mostly on communities of interacting populations, however circumscribed. While a community can include species thrown together by locale that do not necessarily interact, community ecology generally emphasizes the wide diversity of species interactions that exist within the area.

Community ecologists investigate interactions under numerous labels and categories, including on-going studies of traditional topics such as predation, **competition**, trophic exchanges, and others. Borrowing concepts from other disciplines, such as physics, ecologists are also beginning to look closely at the linkages and assemblages that emerge from strong versus weak interactions, or from positive compared to negative interactions. Researchers continue to investigate the relative importance of intra-species and inter-species interactions in terms of their importance to community composition and rates of **succession**. One recent study, for example, analyzed the importance of interspecific interactions in the structuring of the geographical distribution and abundance of a tropical stream fish community.

The importance of trophic relationships and food web dynamics have always been recognized by ecologists, but a recent article in the journal *Ecology* can still suggest that "a step toward understanding the dynamics of communities is to describe the pathways along which feeding interactions occur." Ecologists are beginning to quantify feeding interactions, and are moving far beyond the old, linear food chain studies to recognize the complex, multiple linkages created by the feeding relationships among large assemblages of species. Current research also recognizes the composite effects that trophic interactions have on the whole community.

One example of the significance of feeding relationships is the continuing role of predation in community ecology. A study might conclude that "Alaskan kelp forests are broadly dependent on **sea otter** predation for protection against destructive grazing." Another might look at the timing of predation, and conclude that "temporal variability in predation by whelks can have distinctive effects on prey, create distinctive community compositions, and affect successional paths in [an] intertidal community."

Community ecologists still emphasize species interactions that have been prominent through all the decades of field research. Ecologists still claim, for example, that "assumptions about competition lie at the heart of several models of plant community organization." Other articles in the same journal *Ecology* reinforce this emphasis, stating e.g., "that competition is pervasive in the [Chihuahuan **desert** rodent] community." Another example, in the *Journal of Ecology* indicates that "interspecific competition may limit the growth, branching, survival and berry production by Vaccinium dwarf shrubs in a subarctic plant community."

The degree of pattern or randomness of community structure has long been an issue in community ecology. Natural communities are immensely complex and it is difficult to simplify this complexity down to useable, predictive models. Researchers continue to investigate the extent to which species' interactions can result in a unit organized enough to be considered a coherent community. The mechanics of community assembly depend heavily on invasions, rates of succession, and on changes in the physical environment, as well as a diversity of co-evolutionary patterns.

A debate still continues among community ecologists about the importance of complexity, the role of species diversity and richness in the maintenance of a community. Community structure patterns might be dependent, in part, on factors as seemingly trivial as seed weight. **Accuracy** in estimations of the number of species in a given community is difficult, including the large number of **microorganisms** as yet unidentified and unnamed. Statistical inference can help to dilute this issue somewhat.

Disturbances and perturbations are important factors in the composition and character of communities. One study may focus on the role of fire in tall tussock **grasslands**. Another recent study of old-growth forests in British Columbia concluded that "small-scale natural disturbances involving the death of one to a few trees and creating gaps in the forest canopy are key processes in the...community ecology of many forests." In the recent "landscape view" emerging in

ecology, some research indicates that natural communities may persist in patches, as long as they remain interconnected. This underlines again the importance of context in any attempt to understand community ecology.

The most significant source of disturbance and change in natural communities is human activity. Recent studies in community ecology have documented the impact of human removal and then reintroduction of a **keystone species** such as largemouth bass into a lake; have questioned the impact of "importing" an alien seaweed from Japan to expand Brittan's kelp farms; and have indicated that "human fishing pressure has influenced Caribbean **coral reef** community structure by affecting predator-herbivore relationships." Humans can also have positive effects through deliberate attempts to offset destructive impacts. A recent study published in the journal *Nature* described the deliberate modification of **pH** levels in lakes by adding phosphate **fertilizer**, which reversed **acidification** without "drastically altering the community structure." Such manipulations, modifications, alterations, and disruptions by humans could obviously be expanded into a very long list, but the idea should be clear.

One other type of human impact, however, is receiving a lot of attention: evidence is mounting that **climate** change is increasingly impacting natural communities. For example, one recent study suggested that "increased warming could change the dominant vegetation of a widespread meadow **habitat**, changing the competitive relationships between sagebrush and cinquefoil." Another indicated that "regional climatic warming may be altering the species composition of Alaskan arctic tundra" through changes in light, temperature and nutrients that affect community and ecosystem processes.

The information gained in community ecology studies is becoming increasingly important to achieving **conservation** objectives and establishing guidelines to management of the natural systems on which all humans depend. For example, clearer understanding of linkages established in communities through trophic exchanges can help predict the impacts of concentrations of **toxins** and pollutants. Better understanding of organismic interactions in a community context can help in comprehending the processes that lead to **extinction** of species, information critical to attempts to slow the loss of biological diversity. Research into community dynamics can result in better decisions about establishing preserves and refuges, and can create sustainable harvesting strategies.

The professional ecology journals do not publish research on the importance of community for the human species. Yet, few concepts are more significant in human affairs than the role of different kinds of community in establishing ties and linkages among human individuals and between humans and the locales in which they live. Equally important is the lack of community, the looseness of ties and the alienation from locale and from others that stem from failures to establish a sense of community. As in natural communities, interactions among human individuals create community and are in turn shaped by community.

Compaction

Compaction is the mechanical pounding of **soil** and weathered rock into a dense mass with sufficient bearing strength or impermeability to withstand a load. It is primarily used in construction to provide ground suitable for bearing the weight of any given structure. With the advent of huge earth-moving equipment we are now able to literally move mountains. However, such disturbances loosen and expand the soil. Thus soil must be compacted to provide an adequate breathing surface after it has been disturbed. Inadequate compaction during construction results in design failure or reduced service life of a structure. Compaction, however, is detrimental to crop production because it makes root growth and movement difficult, and deprives the soil of access to life-sustaining oxygen.

With proper compaction we can build enduring roadways, airports, **dams**, building foundation pads, or clay liners for secure landfills. Because enormous volumes of ground material are involved, it is far less expensive to use on-site or nearby resources wherever feasible. Proper engineering can overcome material deficiencies in most cases, if rigid quality control is maintained.

Successful compaction requires a combination of proper moisture conditioning, the right placement of material, and sufficient pounding with proper equipment. Moisture is important because dry materials seem very hard, but they may settle or become **permeable** when wet. Because of all the variables involved in the compaction process, standardized laboratory and field testing is essential.

The American Society of State Highway **Transportation** Officials (ASHTO) and the American Society of Testing Materials (ASTM) have developed specific test standards. The laboratory test involves pounding a representative sample with a drop-hammer in a cylindrical mold. Four uniform samples are tested, varying only in moisture content. The sample is trimmed and weighed, and portions oven-dried to determine moisture content.

The results are then graphed. The resultant curve normally has the shape of an open hairpin, with the high point representing the maximum density at the optimum moisture content for the compactive effort used. This curve reflects the fact that dry soils resist compaction, and overly-moistened soils allow the mechanical energy to dissipate. Field densities must normally meet 95% or higher of this lab result.

Because soils are notoriously diverse, several different "curves" may be needed; varied materials require the field engineer to exercise considerable judgment to determine the proper standard. Thus the field engineer and the earth-moving crew must work closely together to establish the procedures for obtaining the required densities.

In the past, density testing has required laboriously digging a hole, and comparing the volume with the weight of the material removed. Nuclear density gages have greatly accelerated this process and allow much more frequent testing if needed or desired. To take a reading, a stake is driven into the ground to form a hole into which a sealed nuclear probe can be lowered.

It is much easier to properly compact materials during construction than to try to make corrections later. A well-compacted, properly tested structure is an investment in the future, well worth the time and effort expended.

Comparative risk

Initiated by the United States Environmental Protection Agency's (EPA) federal Comparative Risk Project in 1986, comparative risk projects by the end of the twentieth century, there were 46 projects underway. Furthermore, today the priority setting method had gained national attention as many members of Congress, federal professionals, and policy experts agree that environmental protection and public health agencies should, when setting priorities, consider the relative degree of risk their actions will reduce. However, while proponents tout comparative risk as a rational approach to making decisions about priorities, critics among national and grassroots environmental organizations believe that comparative risk ranking can be a "hard" technocratic approach that ignores non-risk factors in decision making, is "undemocratic," and is contrary to **pollution** prevention or the will of the people.

In the past, risk has not been factored into environmental priority setting and, as remarked by William Ruckelshaus, who twice served as EPA administrator, it "was hardly mentioned in the early years of EPA, and it does not have an important place in the Clean Air or Clean Water Acts passed in that period." But, building on Ruckelshaus's groundwork in comparative risk, EPA Administrator Lee Thomas helped thrust the concept onto the national agenda in 1986 when he asked 75 agency professionals to examine 31 environmental problems in the areas of **cancer**, non-cancer, and ecological risks as well as welfare effects (**visibility** impairment, damage to statuary from **acid rain**, etc.). In their 1987 report to Thomas, *Unfinished Business: A Comparative Assessment of Environmental Problems*, the professionals reported that, "Overall, EPA's priorities appear more closely aligned with public opinion than with our estimated risks." For instance, the EPA professionals regarded indoor **air pollution** and global warming as relatively high risks and contaminated **hazardous waste** sites as relatively low risk problems, while opinion polls showed that the public had an opposite ranking. In releasing the report, Thomas noted that EPA has finite resources and therefore must choose its priorities carefully "so that we apply those resources as effectively as possible" in reducing risks. The EPA report became the first significant study suggesting that national environmental priorities were inconsistent with the experts' sense of the most serious environmental problems, and instead the nation's priorities were guided by public perceptions of risk.

Concerns about the growing number of environmental regulations and problems demanding attention, coupled with the decline in resources to spend on these problems, kept up the pressure for EPA, states, and local governments to find a rational approach for deciding where to target finite resources. The publication of a report in 1991, *Environmental Investments: The Cost of a Clean Environment*, reinforced these concerns. That report was a first estimation of the costs that industries and municipalities must incur through compliance with federal **pollution control** programs. In 1991, costs were $115 billion a year—2.1% of the Gross National Product (GNP)—but were projected to rise to $185 billion or 2.8% of the GNP by the year 2000.

In late 1991, Senator Daniel Patrick Moynihan (D-N.Y.) introduced a bill (S.2132) that would have required EPA to seek the advice of experts in ranking relative risks and to use that information in managing its available resources to protect society from the greatest risks. Moynihan's bill, and its successor in the 103rd Congress, became important elements of the debate over whether risk-based "rational" priority setting should be required to ensure more efficient risk reduction.

Even before the 1991 EPA report on the rising costs of environmental protection, EPA Administrator William K. Reilly had taken up comparative risk as a central theme of his administration and had asked the agency's Science Advisory Board to review the report issued by the 75 agency professionals. The board's response, a 1990 report called *Reducing Risk: Setting Priorities And Strategies For Environmental Protection*, also recommended that EPA and other government agencies "assess the range of environmental problems of concern and then target protective efforts at problems that seem to be the most serious." Far and away the greatest expenditures of EPA resources were directed at the agency's construction grants program for publicly owned **wastewater** treatment plants and the cleanup of abandoned Superfund sites—for instance, a full 70% of the agency's fiscal year 1990 budget of $6 billion went to these programs—even though other problems were deemed more serious from a scientific perspective. The science advisors also suggested that EPA should give more attention to the relatively neglected job of protecting ecosystems, which faced high risks from **habitat** alteration, loss of **biodiversity**, global **climate** change, and **ozone layer depletion**.

Reducing Risk, and the general topic of whether "Worst Things First" should be the touchstone of environmental priority setting, was debated at a November 1992 meeting in Annapolis, Maryland, at which critics challenged its "quasi-scientific" claims and offered competing priority setting approaches, including a strategy that would make preventing pollution the fundamental criterion for **environmental policy** decisions founded on the public's decision that pollution is undesirable. In the critics' view, comparative **risk analysis** presumes that some pollution and its risk is acceptable.

Skepticism notwithstanding, EPA chose to foster development of the method. As part of its endorsement of comparative **risk assessment** as an important priority setting tool, EPA promoted a series of comparative risk projects in several of its regions—Region 1, New England; Region 3, the Mid-Atlantic states; and Region 10, the Pacific Northwest—and in three pilot states: Washington, Colorado, and Pennsylvania. Later, Vermont, California, Utah, Michigan, and other states joined in. Sub-state entities also developed projects, including Columbus, Ohio; Atlanta, Georgia; Elizabeth River, Virginia; Houston, Texas; and Wisconsin tribes.

Typically, comparative risk projects follow six basic steps. First, they define and analyze the risks posed by environmental problems facing the jurisdiction, usually working from a list of problems. Second, they rank the problems according to the relative severity of each, using technical information and criteria to grade the negative impacts of individual problems on health, ecosystems, or quality of life. Third, they select priorities for special attention and set goals for reducing risks posed by the problem. Fourth, they propose, analyze, and compare strategies for achieving the goals set in step three. Fifth, they implement strategies having the greatest risk-reduction promise. And, sixth, they monitor results produced by the strategies and adjust jurisdictional policies or budgets based on those results. These steps are carried out through committees composed of state or local officials, industry representatives, environmentalists, and citizens. The projects all seek to broadly incorporate public values—not merely technical scientific information—in assessing and ranking risks.

Among the more widely cited state comparative risk projects is Washington Environment 2010, which, more than any other state project, influenced legislation and state policy. It was initiated in 1988 by Washington's Department of Ecology Director Christine Gregoire and included technical committees with members from 19 state agencies and a steering committee composed of senior managers or heads of those agencies. In addition, it had a public advisory committee composed of 34 prominent legislators, representatives, and important interest groups. Resulting from this project was a ranking of 23 threats to the environment within five priority levels. **Ambient air** pollution, point-source discharges of pollution to water, and polluted **runoff** ranked as the top priorities, and non-ionizing radiation, materials storage in tanks, and litter ranked as the lowest priorities. Based on the project, and a statewide effort to solicit public responses that produced some 300 risk-reduction options, Washington's legislature in 1991 adopted several new environmental laws dealing with clean air, **transportation** demand, **water conservation**, **recycling**, growth management, and the state's **energy policy**. The Department of Ecology redirected $6.8 million of its budget from lower to higher risk priorities. However, in 1993 Gregoire's successor reorganized the department, dismantling an Environment 2010 planning staff that had been established and, with it, the state's institutional memory of the comparative risk project. Washington's experience in this regard, and similar experiences in other states, have made some proponents of comparative risk assessment question how deeply and lastingly its effects will be felt in environmental programs.

Despite such setbacks, the comparative risk concept has continued to find a significant place in governmental discussions of environmental policy. In 1993, the White

House of Science and Technology Policy and the **Office of Management and Budget** invited comparative risk analysis experts to meet with federal government officials to explore how the approach could be used by federal agencies to establish broad priorities more systematically. That effort resulted in a 1996 report, *Comparing Environmental Risks: Tools for Setting Government Priorities*, that proposed a basic framework for using the method in federal agencies. Furthermore, during the 104th Congress, comparative risk analysis was one of numerous risk-related reforms that were included in the Republican Contract With America and its agenda of reducing regulatory burdens through a downsizing of government, the most far-reaching attempt to impose a "rational" risk-based priority setting system on federal agencies.

While the future of comparative risk analysis as a basis for establishing environmental priorities remains uncertain, federal, state, and local interest remains strong. Today, most practitioners and proponents of the approach recognize that comparative risk alone will not suffice to establish priorities. Public values, hard to quantify benefits, and other non-scientific elements that must be weighed in decisions about priorities have a clearly recognized role. That conclusion has been reinforced in all the state and local projects. Some recent studies suggest that the future progress of comparative risk analysis requires more research on how to better inform diverse parts of the affected public throughout the process of setting environmental priorities. Even though federal legislation that would mandate comparative risk analysis as a basis for selecting priorities may never pass, the risk-based approach enunciated in 1987 has emerged today as a central piece of environmental policy and is explicitly discussed in EPA's draft *Environmental Goals for America With Milestones for 2005*, the latest federal effort to clarify and organize environmental priorities.

Competition

Competition is the interaction between two organisms when both are trying to gain access to the same limited resource. When both organisms are members of the same **species**, such interaction is said to be "intraspecific competition." When the organisms are from different species, the interaction is "interspecific competition."

Intraspecific competition arises because two members of the same species have nearly identical needs for food, water, sunlight, nesting space, and other aspects of the **environment**. As long as these resources are available in abundance, every member of the community can survive without competition. When those resources are in limited supply, however, competition is inevitable. For example, a single nesting pair of bald eagles requires a minimum of 620 acres (250 ha) that they can claim as their own territory. If two pairs of eagles try to survive on 620 acres, competition will develop, and the stronger or more aggressive pair will drive out the other pair.

Intraspecific competition is also a factor in controlling plant growth. When a mature plant drops seeds, the seedlings that develop are in competition with the parent plant for water, sunlight, and other resources. When abundant space is available and the size of the community is small, a relatively large number of seedlings can survive and grow. When population density increases, competition becomes more severe and more seedlings die off.

Competition becomes an important limiting factor, therefore, as the size of a community grows. Those individuals in the community that are better adapted to gain food, water, nesting space, or some other limited resource are more likely to survive and reproduce. Intraspecific competition is thus an important factor in natural selection.

Interspecific competition occurs when members of two different species compete for the same limited resource(s). For example, two species of birds might both prefer the same type of insect as a food source and will be forced to compete for it if it is in limited supply.

Laboratory studies show that interspecific competition can result in the **extinction** of the species less well adapted for a particular resource. However, this result is seldom, if ever, observed in **nature**, at least among animals. The reason is that individuals can adapt to take advantage of slight differences in resource supplies. In the Galapagos Islands, for example, 13 similar species of finches have evolved from a single parent species. Each species has adapted to take advantage of some particular **niche** in the environment. As similar as they are, the finches do not compete with each other to any specific extent.

Interspecific competition among plants is a different matter. Since plants are unable to move on their own, they

are less able to take advantage of subtle differences in an environment. Situations in which one species of plant takes over an area, causing the extinction of competitors, are well known.

One mechanism that plants use in this battle with each other is the release of toxic **chemicals**, known as allelochemicals. These chemicals suppress the growth of plants in other—and, sometimes, the same—species. Naturally occurring antibiotics are examples of such allelochemicals.

Competitive exclusion

Competitive exclusion is the interaction between two or more **species** that compete for a resource that is in limited supply. It is n ecological principle involving competitors with similar requirements for **habitat** or resources; they utilize a similar **niche**. The result of the **competition** is that one or more of the species is ultimately eliminated by the species that is most efficient at utilizing the limiting resource, a driving force of **evolution**. The competitive exclusion principle or "Gause's principle" states that where resources are limiting, two or more species that have the same requirements for the limiting resources cannot co-exist. The co-existing species must therefore adopt strategies that allow resources to be partitioned so that the competing species utilize the resources differently in different parts of the habitat, at different times, or in different parts of the life cycle.

[*Marie H. Bundy*]

Composting

Composting is a fermentation process, the break down of organic material aided by an array of **microorganisms**, earthworms, and other insects in the presence of air and moisture. This process yields compost (residual organic material often referred to as **humus**), ammonia, **carbon dioxide**, sulphur compounds, volatile organic acids, water vapor, and heat. Typically, the amount of compost produced is 40–60% of the volume of the original waste.

For the numerous organisms that contribute to the composting process to grow and function, they must have access to and synthesize components such as **carbon**, **nitrogen**, oxygen, **hydrogen**, inorganic salts, sulphur, **phosphorus**, and trace amounts of micronutrients. The key to initiating and maintaining the composting process is a carbon-to-nitrogen (C:N) ratio between 25:1 and 30:1. When **C:N ratio** is in excess of 30:1, the **decomposition** process is suppressed due to inadequate nitrogen limiting the **evolution** of bacteria essential to break the strong carbon bonds. A C:N ratio of less than 25:1 will produce rapid localized decomposition with excess nitrogen given off as ammonia, which is a source of offensive odors.

Attaining such a balance of ratio and range is possible because all organic material has a fixed C:N ratio in its tissue. For example, **food waste** has a C:N ratio of 15:1, sewage **sludge** has a C:N ratio of 16:1, grass clippings have a C:N ratio of 19:1, leaves have a C:N ratio of 60:1, paper has a C:N ratio of 200:1, and wood has a C:N ratio of 700:1. When these (and other) materials are mixed in the right proportions, they provide optimum C:N ratios for composting. Typically, nitrogen is the limiting component that is encountered in waste materials and, when insufficient nitrogen is present, the composting mixture can be augmented with agricultural fertilizers, such as urea or ammonia nitrate.

In addition to nutrients, the efficiency of the composting process depends on the organic material's size and surface characteristics. Small particles provide multi-faceted surfaces for microbial action. Size also influences porosity (crevices and cracks which can hold water) and permeability (circulation or movement of gases and moisture).

Moisture (water) is an essential element in the biological degradation process. A moisture level of 55–60% by weight is required for optimal microbial, **nutrient**, and air circulation. Below 50% moisture, the nutrients to sustain microbial activity become limited; above 70% moisture, air circulation is inhibited.

Air circulation controls the class of microorganisms that will predominate in the composting process: air-breathing microorganisms are collectively termed **aerobic**, while microorganisms that exist in the absence of air are called **anaerobic**. When anaerobic microorganisms prevail, the composting process is slow, and unpleasant-smelling ammonia or hydrogen sulfide is frequently generated. Aerobic microorganisms will quickly decompose organic material into its principal components of carbon dioxide, heat and water.

The role of acidity and alkalinity in the composting process depends upon the source of organic material and the predominant microorganisms. Anaerobic microorganisms generate acidic conditions which can be neutralized with the addition of lime. However, such adjustments must be done carefully or nitrogen imbalance will occur that can further inhibit biological activity and produce ammonia gas, with its associated unpleasant odor. Organic material with a balanced C:N ratio will initially produce acidic conditions,

6.0 on the **pH** scale. However, at the end of the process cycle, mature compost is alkaline, with a pH reading greater than 7.0 and less than 8.0.

The regulation and measurement of temperature is fundamental to achieving satisfactory processing of organic materials. However, the effect of ambient or surface temperatures on the process is limited to periods of intense cold when biological growth is dormant. Expeditious processing and reduction of herbicides, pathogens, and pesticides is achieved when internal temperatures in the compost pile are maintained at 120–140°F (55–l60°C). If the internal temperature is allowed to reach or exceed 150°F (65°C), biological activity is inhibited due to heat stress. As the nutrient content is depleted, the internal temperature decreases to 85°F (30°C) or less–one criteria for defining mature or stabilized compost.

Mature or stabilized compost has physical, chemical, and biological properties which offer a variety of attributes when applied to a host **soil**. For example, adding compost to barren or disturbed soils provides organic and microbial resources. The addition of compost to clay soils enhances the movement of air and moisture. The water retention capacity of sandy soil is enhanced by the addition of compost and **erosion** also is reduced. Soils improved by the addition of compost also display other characteristics such as enhanced retention and exchange of nutrients, improved seed germination, and better plant root penetration. Compost, however, has insufficient nitrogen, phosphorous, and potassium content to qualify as a **fertilizer**. The ultimate *application* or *disposition* of compost depends upon its quality, which is a function of the type of organic material and the method(s) employed to enhance or control processing.

Compost processing can be as simple as a plastic **garbage** bag filled with a mixture of plant waste that has had a couple of ounces of fertilizer, some lime, and sufficient water added to make the material moist. The bag is then sealed and set aside for about 12 months. Faster processing can be achieved with the use of a 55 gal (208 l) drum into which 0.5-in (1.3-cm) holes have been drilled for air circulation. Filled with the same mixture as the garbage bag and rotated at regular intervals, this method will produce compost in two to three months. A multi-compartmentalized container is faster and increases the diversity of materials which can be processed. However, including such items as fruit and vegetable scraps, meat and dairy products, cardboard cartons, and fabrics must be undertaken with caution because they attract and breed vermin.

Such methods are designed for individual use, especially by those who can no longer dispose of garden waste with their **household waste**. Similarly, commercial and government institutions employ natural (low), medium, and advanced technical composting methods, depending on their motivation, i.e., diminishing **landfill** capacity, availability of fiscal resources, and commitment to **recycling**. The simplest composting method currently employed by industry and municipalities entails dumping **organic waste** on a piece of land graded (sloped) to permit precipitation and leachate (excess moisture and organics from composting) to collect in a retention pond. The pond also serves as a source of moisture for the compost process and as a system where **photosynthesis** can oxidize the leachate. The organic material is placed in piles called *windrows* (a ridge pile with a half-cone at each end). The dimensions of a windrow are typically 10–12 ft (3–3.7 m) wide at the base and about 6 ft (1.8 m) high at the top of the ridge. The length is site specific. Windrows are constructed using a front-end loader. A mature compost will be available in 12–24 months, depending on various factors including the care with which the organic material was blended to obtain optimum C:N ratio; the supplementation of the material with additional nutrients; the frequency of **aeration** (mixing and turning); and the moisture content maintained.

Using the same site layout, the next step in mechanization is the use of windrow turners. These turners can be simple aeration machines or machines with the added ability to shred material into smaller particles, while injecting supplemental moisture and/or nutrients. Optimizing the capabilities of such equipment requires close attention to temperature variation within the windrows. Typically, the operator will use a temperature probe to determine when the temperature falls in the range of 100°F (37–38°C). The equipment will then fold the outer surface of the windrow inward, replenishing air and moisture, and mixing in unconsumed or supplemental nutrients. This promotes further decomposition, which is identified by a gradual rise in temperature. Sequential turning and mixing will continue until temperatures are uniformly diminished to levels below 85°F (30°C). This method produces a mature compost in four to eight months.

Two more technologically advanced composting methods are the *in-vessel system* and the *forced-air system*. Both are capable of processing the bulk of all solid and liquid municipal wastes. However, such flexibility imposes substantial capital, technical, and operational requirements. In forced air processing, organic material is placed on top of a series of perforated pipes attached to fans which can either blow air into, or draw air through the pile to control its temperature, oxygen, and carbon dioxide needs. This system is popular for its ability to process materials high in moisture and/or nitrogen content, such as yard wastes. Time to produce a mature compost is measured in days, depending on the class of organic material processed. During in-vessel processing, organic material is continuously fed into an inclined rotating cylinder, where the temperature, moisture,

A man adds moisture to mushroom compost. (Photograph by Holt Confer. Phototake. Reproduced by permission.)

and nutrient air and gas levels are closely controlled to achieve degradation within 24–72 hours. The composted material is then screened to remove foreign or inert materials such as glass, **plastics**, and metals and is allowed to mature for 21 days.

Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)

In response to **hazardous waste** disasters such as **Love Canal**, New York, in the 1970s, Congress passed the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), better known as Superfund, in 1980. The law created a fund of $1.6 billion to be used to clean up hazardous waste sites and hazardous waste spills for a period of five years. The primary source of support for the fund came from a tax on chemical feedstock producers; general revenues supplied the rest of the money needed. CERCLA is different from most environmental laws because it deals with past problems rather than trying to prevent future **pollution**, and because the **Environmental Protec-**

tion Agency (EPA), in addition to acting as a regulatory agency, must clean up sites itself.

Throughout the decade before the creation of Superfund, the public began to focus increasing attention on hazardous wastes. During this period, an increased number of cases involving such wastes contaminating drinking water, streams, rivers, and even homes were reported. Citizens were enraged by dangers posed by leaking landfills, illegal dumping of hazardous wastes along roads or in vacant lots, and explosions and fires at some facilities.

A strong catalyst for hazardous waste regulation was the Love Canal episode near Niagara Falls, New York. In the late 1970s, chemical wastes from an abandoned dump were discovered in the basements of some homes. Studies found significant health effects, including miscarriages and low-weight newborns. Residents worried about increased **cancer** and birth defect rates. In the federal emergency declaration, a school and 200 houses were condemned. The combination of public concern and media coverage, together with EPA interest, brought national attention to this issue.

Debate soon began over proper government response to these problems. Industrial interests argued that a company should not be liable for cleaning up past hazardous waste dumps if it had not violated any law in disposing of the wastes. The industry argued that general taxes, not industry-specific taxes, should be used for the clean-up, and it sought to limit the legal liability of manufacturers in regard to the health effects of their hazardous wastes. Industrial companies also pushed for one national regulatory program, rather than a national program and several state programs to complicate the situation.

When Congress began debating a Superfund program in 1979, EPA officials argued that industry must pay the bulk of the clean-up costs. They based this argument on the philosophy that the polluter should pay, and also the pragmatic reasoning that Congress could not be relied on to continue appropriating the funds needed for such an expensive and lengthy program. The Senate focused on a comprehensive bill that included provisions for liability and **victims' compensation**, but these were dropped in order to secure passage of the program through the House. The act was signed by President Carter in December 1980.

Under the law, the EPA determines the most dangerous hazardous waste sites, based on characteristics like toxicity of wastes and risk of human exposure, and places them on the **National Priorities List** (NPL), which determines priorities for EPA efforts. The EPA has the authority to either force those responsible for the site to clean it up, or clean up the site itself with the Superfund money and then seek to have the fund reimbursed through court action against the responsible parties. If more than one company had dumped wastes at a site, the agency is able to hold one party responsible for all clean-up costs. It is then up to that party to recover its costs from the other responsible parties. If those identified as responsible by the EPA deny their responsibility in court and lose, they are liable for treble damages. Removal actions, emergency clean-ups, or actions costing less than $2 million and lasting less than a year, can be undertaken by the EPA for any site. For federal hazardous waste sites, the clean-up must be paid for through the appropriation process rather than through Superfund. States are required to contribute 10 to 50 percent of the cost of clean-ups within their boundaries; they are also responsible for all operation and maintenance costs once the job is finished. The EPA can also delegate lead clean-up authority to the states.

Major amendments to CERCLA were passed in 1986. As the scope of the problem grew, Congress re-authorized the Superfund through 1991 and increased its size to $8.5 billion. Plans indicated that the enlarged Superfund would be financed by taxes on **petroleum**, feedstock **chemicals**, corporate income, general revenue, interest from money in the fund, and money recovered from companies responsible for earlier clean-ups. The amendments required several areas of compliance: 1) The clean-ups must meet the applicable state and federal environmental standards; 2) The EPA must begin clean-up on at least 375 sites by 1991; 3) Negotiated settlements for clean-ups are preferred to court litigation; 4) Emergency procedures and community **right-to-know** standards, are required in areas with hazardous waste facilities (largely in response to the **Bhopal, India** toxic gas disaster); and 5) Federal agencies must comply with Superfund Amendments and begin the clean-up of federal facilities and sites. The 1991 Superfund Amendments and Reauthorization Act authorized a four-year extension of the taxes that financed Superfund, but the law was not changed significantly.

As of August 1990, 33,000 sites were listed as being potentially hazardous, 1,082 sites were on the NPL, and over 100 sites were proposed by the EPA to be added to the list. Of the sites that required preliminary EPA investigation, over 90% had been examined, but actual clean-up has been rather slow. In mid-1990, clean-up had been completed at only 54 NPL sites. However, funding had been approved for planning studies at over 1,000 sites, design work at over 400 sites, and remedial work at over 280 sites. Removal actions by the EPA or responsible parties had taken place at over 1,500 sites, most of which were not on the NPL.

Studies of Superfund implementation have been quite critical. Reports by Congressional committees, the General Accounting Office, and the Office of Technology Assessment (OTA) concluded that the EPA relied on temporary rather than permanent treatment methods, took too long to clean up sites because of poor management, too frequently

opted to use the Superfund for clean-ups rather than requiring responsible parties to pay, and often lacked the expertise to oversee Superfund clean-up operations. In reality, early implementation efforts of Superfund were hampered by uncommitted EPA officials, lack of financial and staff resources, poor government coordination of policy objective, and by the complexity of identifying and exacting payment from responsible parties.

Another problem had been the amount of expensive and time-consuming litigation involved in the act. In some cases litigation costs to determine responsible parties and recover clean-up costs has exceeded the cost of clean-up itself. Between 1986 and 1988, the EPA only recovered 7% of what it spent on clean-up from private parties.

Implementation of CERCLA has also been marked by charges of corruption and political manipulation. Rita Lavelle, who was in charge of the Superfund program at EPA, resigned in 1983 amid charges that she was giving unduly favorable treatment to industry. She was later convicted on perjury charges. Also in 1983, EPA Administrator Anne Gorsuch Burford resigned, largely in response to the difficulties of Superfund implementation.

Thus far, CERCLA has proved to be a more complicated, costly, and time-consuming process than originally envisioned. A 1988 Congressional report estimated that between $16.7 and $23.8 billion of federal money would be needed to clean up the less than 1,000 sites then on the NPL. A 1989 OTA report estimated the cost of the program to be $500 billion in the long run, with as many as 10,000 sites eventually being placed on the NPL. *See also* Hazardous material; Hazardous Materials Transportation Act; Hazardous Substances Act; Hazardous waste site remediation; Hazardous waste siting; Toxic substances

Computer disposal

Because computer technology changes so quickly, the average computer sold in the United States in the early 2000s becomes obsolete in only three years. Consumers were expected to retire about 50 million computers in 2002. One government survey reported that 75% of all the computers ever sold in the United States were stockpiled by 2001, not disposed of even though their useful life is over. Computers and other electronics account for about 220 million tons of waste annually, according to the United States **Environmental Protection Agency** (EPA). Some older computers find new users when they are passed on to nonprofit groups, schools, or needy families. Some manufacturers arrange to take back their out-of-date products. Approximately 10% of outdated computers are recycled.

Computers contain a variety of materials, some of them toxic. If computers are not recycled but disposed of in landfills, valuable material is wasted, and **toxins**, particularly **lead** and **mercury**, may present a hazard to people and the **environment**. As many consumers are still storing two or three older computers, the number of computers currently in the **waste stream** is only a fraction of what it might be, so computer disposal is a looming problem.

In the United States, the electronics industry, **conservation** groups, and government organizations began working toward a satisfactory system of computer disposal in the early 2000s. The Japanese government enacted a computer **recycling** law in 2001, and the **European Union** passed* similar legislation, that will take effect in the middle of the decade.

A typical computer consists of 30–40% plastic. The plastic may be of several different types. Unlike the plastic in food and beverage containers, which is usually given a number to identify it and make recycling easier, plastic in computers is unlabeled. A computer may contain over four pounds of lead, as well as small amounts of the toxic metals mercury and **cadmium** and traces of other metals including gold, silver, steel, **aluminum**, **copper**, and **nickel**.

Recycling a computer is not a simple process, and is also quite expensive. To recycle a computer it must be broken into parts, and its usable materials separated. Plastic used for computers can be recovered, reprocessed into pellets, and sold for re-use. The metals also can be recovered, although the process itself can generate dangerous waste. For instance, gold can be stripped off computer chips with a wash of hydrochloric **acid**. The acid must then be treated or stored safely, or it can contaminate the environment.

Recycling is not an easy solution to the problem of computer disposal. However, a few companies in the United States have found electronics recycling to be a profitable business. A report compiled by two West Coast environmental groups in 2002 found that up to 80% of computers collected for recycling in California and other western states ended up in **third world** countries, where parts were often salvaged by low-paid workers. Not only were workers often

unprotected against toxic materials, but toxic waste was dumped directly into lakes and streams, the report detailed.

Some government and conservation groups have suggested that the computer industry try to reduce toxic waste by redesigning its products. Labeling of **plastics** used would simplify plastic recycling, as would phasing out some more harmful materials and toxic fire-retardant coatings. Making computers with parts that snap together instead of using glue or metal nuts and bolts is another design consideration that can make computers easier to recycle. A number of major manufacturers, including Dell Computer and IBM, began their own recycling programs in the early 2000s. A coalition of industry, environmental, and government groups called the National Electronics Product Stewardship Initiative began meeting in 2001 to come up with national guidelines for computer disposal. The high cost of computer recycling is expected to decline somewhat as the volume of recycled machines rises. Because of the vast backlog of computers in the United States waiting to be thrown out, it is imperative to work out a system for safe disposal quickly.

Condensation nuclei

When air is cooled below its **dew point**, the water vapor it contains tends to condense as droplets of water or tiny ice crystals. Condensation may not occur, however, in the absence of tiny particles on which the water or ice can form. These particles are known as condensation nuclei. The most common types of condensation nuclei are crystals of salt, **particulate** matter formed by the **combustion** of **fossil fuels**, and dust blown up from the earth's surface. In the process of cloud-seeding, scientists add tiny crystals of dry ice or silver iodide as condensation nuclei to the **atmosphere** to promote cloud formation and precipitation.

Congo River and basin

The Congo River (also known as the Zaire River) is the third longest river in the world, and the second longest in Africa (after the Nile River in northeastern Africa). Its river basin, one of the most humid in Africa, is also the largest on that continent, covering over 12% of the total land area.

History

The equatorial region of Africa has been inhabited since approximately the middle Stone Age. Late Stone Age cultures flourished in the southern savannas after about 10,000 B.C. and remained functional until the arrival of Bantu-speaking peoples during the first millennium B.C. In a series of migrations taking place from about 1,000 B.C. to the mid-first millennium A.D., many Bantu-speakers dispersed from an area west of the Ubangi-Congo River swamp across the forests and savannas of the region known as the modern-day Democratic Republic of the Congo.

In the precolonial era, this region (modern-day Democratic Republic of the Congo) was dominated by three kingdoms: Kongo (late 1300s), the Loango (at its height in the 1600s), and Tio. Portugese navigator Diogo Cam was the first European to sail up the mouth of the Congo in 1482. After meeting with the rulers of the Kingdom of Kongo, Cam negotiated intercontinental trade and commerce agreements—including the slave trade—between Portugal and the region. And a long history of colonialism began.

Over the centuries, the Congo River has inspired both mystery and legend, from the explorations of Henry Morton Stanley and David Livingstone in the 1870s, to Joseph Conrad, whose novel, *Heart of Darkness* transformed the river into an eternal symbol of the "dark continent" of Africa.

Characteristics

The Congo River is approximately 2,720 mi long (4,375 km), and its **drainage** basin consists of about 1.3 million mi^2 (3.6 million km^2). The basin encompasses nearly the entire Democratic Republic of the Congo (capital: Kins-

hasa), Republic of Congo (capital: Brazzaville), Central African Republic, eastern Zambia, northern Angola, and parts of Cameroon and Tanzania. The river headwaters emerge at the junction of the Lualaba (the Congo's largest tributary) and Luvua rivers. The flow is generally to the northeast first, then west, and finally south to its outlet into the Atlantic Ocean at Banana, Republic of Congo.

The Congo basin comprises one of the most distinct land depressions between the Sahara **desert** to its north, and the Atlantic Ocean to its south and west. The river's tributaries flow down slopes varying from 900 to 1,500 ft (274 to about 457 m) into the central depression forming the basin. This depression extends for more than 1,200 mi (about 1931 km) from the north to the south, from the Congo Lake Chad **watershed**, to the plateaus of Angola. From the east to west of the depression is another 1,200 mi (about 1931 km)—from the Nile-Congo watershed to the Atlantic Ocean. The width of the Congo River ranges from 3.5 mi (about 5.75 km) to 7 mi (about 11.3 km); and its banks contain natural levees formed by **silt** deposits. During floods, however, these levees overflow, widening the river.

With an average annual rainfall of 1,500 mm of rain (about 60 in), about three-quarters returns to the **atmosphere** by **evapotranspiration**; the rest is discharged into the Atlantic. The river is divided into three main regions: the upper Congo, with numerous tributaries, lakes, waterfalls, and rapids; the middle Congo; and, the lower Congo. The middle Congo is characterized by its seven waterfalls, collectively referred to as **Boyoma** (formerly Stanley) Falls. It is below these falls that navigation on the river becomes possible. The river has approximately 10,000 mi (about 16,000 km) of waterways, creating one of the main **transportation** routes in Central Africa.

Economic and environmental impact

Due to its size and other key elements, the Congo River and its basin are crucial to the ecological balance of an entire continent. Although the Congo water **discharge** levels were unstable throughout the second half of the twentieth century—the hydrologic balance of the river has provided some relief from the **drought** that has afflicted the river basin. This relief occurs even with dramatic fluctuations of rainfall throughout the various terrain through which the river passes.

Researchers have suggested that **soil** geology plays a key role in maintaining the river's discharge **stability** despite fluctuations in rainfall. The sandy soils of the Kouyou region, for example, have a stabilizing effect in their ability to store or disperse water.

In 1999, the World Commission on Water for the twenty-first century, based in Paris and supported by the **World Bank** and the United Nations, found that the Congo was one of the world's cleanest rivers—in part due to the lack of industrial development along its shores until that time. However, the situation is changing.

The rapidly increasing human population threatens to compromise the integrity of Congo basin ecosystems. Major threats to the large tropical rainforests and savannas, as well as to **wildlife**, come from the exploitation of **natural resources**. Uncontrolled **hunting** and fishing, **deforestation** (which causes **sedimentation** and **erosion** near **logging** operations) for timber sale or agricultural purposes, unplanned urban expansion (which increases the potential for an increase in untreated sewage and other sources of **pollution** that could harm nearby freshwater systems), and unrestrained extraction of oil and minerals are some of the major economic and environmental issues confronting the region. And these issues are expected to have a global impact as well.

Wildlife

According to the **World Wildlife Fund**, the Congo River and its basin, also known as the "Congo River and Flooded Forests ecoregion," is home to the most diverse and distinctive group of animals adapted to a large-river **environment** in all of tropical Africa.

The Congo river had no outlet to the ocean during the Pliocene Age (5.4–2.4 million years ago) but was instead a large lake. Eventually, the water broke through the rim of the lake, emerging as a river that passed over rocks through a series of rapids, then entered the Atlantic. Except for the beginning and end of its course, the river is uniformly elevated.

With more than 700 fish **species**, 500 of which are endemic to the river, the Congo basin ranks second only to the Amazon in its diversity of species. Nearly 80% of fish species found in the Congo basin exist nowhere else in the world. The various species live both in the river and its attendant habitats—swamps, nearby lakes, and headwater streams. They feed in a variety of ways: scouring the mud at the river's bottom; eating scales off of live fish; and eating smaller fish. Certain fish have even adapted to the river's muddy waters. For example, some have reduced eye size, or no eyes at all, yet easily maneuver through the swift current. The Congo's freshwater fish are a crucial protein source for Central Africa's population; yet the potential for over-fishing near the urban areas along its banks threatens the available supply.

There are also a wide variety of aquatic mammals—such as unusual species of otters, shrews, and monkeys—that are indigenous to the river basin. Rainforests cover over 60% of the Democratic Republic of the Congo, and represents nearly 6% of the world's remaining forested area, and 50% of Africa's remaining forests. Many of the world's **endangered species** live near the river, including gorillas.

River traffic—war, power, and tourism

At the end of May 2001, the United Nations Security Council announced that the Congo River would finally reopen to commercial traffic after a more than two-year blockage due to the war in the Democratic Republic of the Congo. Because of the desperate state of roads throughout the region—or the complete lack of roads—individuals, business, and other agencies have relied primarily on river transportation.

The river had been divided in two at the front line of warring factions—the government forces and their foreign allies on one side, and the rebels backed by Uganda and Rwanda on the other. Massive starvation resulted from the blockage, halting supplies from the United Nations and other humanitarian aid agencies.

With the drought that was running rampant through the early years of the twenty-first century, and those droughts that were anticipated in some areas of southern Africa, distribution of water remains a major challenge. In the fall of 2000, the Southern African Development Community, a group of Congolese business people, began to look to the Congo River for a solution to these water problems.

These developers launched a plan to pump water from the Congo River, by building two long-distance pipelines (known as the Solomon pipelines)— one across the mouth of the Congo River to Walvis Bay in Namibia, 621 mi (about 1,000 km) away; the other, running through civil war zones. They would supply water to the Middle East by way of Port Sudan, a distance of nearly 1,242 mi (about 2,000 km).

The company initiating the plan, Westrac, claimed that the project would create hundreds of jobs, provide for the building of hospitals along the route, and lay fiber-optic communications links as well—thereby boosting the economy of the region and enhancing the lives of the native population. Detractors of the plan countered that the plan would be cost-prohibitive and hazardous to the environment. According to the California-based International Rivers Network, it was "premature to investigate such a complex plan when simpler and cheaper solutions haven't been fully explored," as reported by Radio Netherlands.

With political issues far from resolved as of 2002, and the potential for widespread pollution if industry and the population exploits the resources of the river, future plans could remain unresolved for decades to come. Yet, Salomon Banamuherem, the Democratic Republic of the Congo's minister of tourism, hoped that the project would tap into another great natural resource of the country and its river—tourism. In its entire history, even in times of peace, the country—Africa's third largest country—has attracted no more than100,000 visitors per year.

Despite unresolved political and economic issues, protecting the biodiverse resources and **ecosystem** of the Congo River and basin is perhaps the most important and challenging task facing this region in the future.

Coniferous forest

Coniferous forests contain trees with cones and generally evergreen needle or scale-shaped leaves. Important genera in the northern hemisphere include pines (*Pinus*), spruces (*Picea*), firs (*Abies*), **redwoods** (*Sequoia*), Douglas firs (*Pseudotsuga*), and larches (*Larix*). Different genera dominate the conifer forests of the southern hemisphere. Conifer forests occupy regions with cool-moist to very cold winters and cool to hot summers. Many conifer forests originated as plantations of **species** from other continents. Among conifer formations in North America are the slow-growing circumpolar **taiga** (boreal), the subalpine-montane, the southern pine, and the Pacific Coast temperate **rain forest**. Softwoods, another name for conifers, are used for lumber, panels, and paper.

Conservation

The philosophy or policy that **natural resources** should be used cautiously and rationally so that they will remain available for **future generations**. Widespread and organized conservation movements, dedicated to preventing uncontrolled and irresponsible exploitation of forests, lands, **wildlife**, and **water resources**, first developed in the United States in the last decades of the nineteenth century. This was a time at which accelerating settlement and resource depletion made conservationist policies appealing both to a

large portion of the public and to government leaders. Since then, international conservationist efforts, including work of the United Nations, have been responsible for monitoring natural resource use, setting up **nature** preserves, and controlling environmental destruction on both public and private lands around the world.

The name most often associated with the United States' early conservation movement is that of **Gifford Pinchot**, the first head of the U.S. **Forest Service**. A populist who fervently believed that the best use of nature was to improve the life of the common citizen, Pinchot brought scientific management methods to the Forest Service. He also brought a strongly utilitarian philosophy, which continues to prevail in the Forest Service. Beginning as an advisor to **Theodore Roosevelt**, himself an ardent conservationist, Pinchot had extensive influence in Washington and helped to steer conservation policies from the turn of the century to the 1940s. Pinchot had a number of important predecessors, however, in the development of American conservation. Among these was George Perkins Marsh, a Vermont forester and geographer whose 1864 publication, *Man and Nature*, is widely held as the wellspring of American environmental thought. Also influential was the work of John Wesley Powell, Clarence King, and other explorers and surveyors who, after the Civil War, set out across the continent to assess and catalog the country's physical and biological resources and their potential for development and settlement.

Conservation, as conceived by Pinchot, Powell, and Roosevelt was about using, not setting aside, natural resources. In their emphasis on wise resource use, these early conservationists were philosophically divided from the early preservationists, who argued that parts of the American **wilderness** should be preserved for their aesthetic value and for the survival of wildlife, not simply as a storehouse of useful commodities. Preservationists, led by the eloquent writer and champion of Yosemite Valley, **John Muir**, bitterly opposed the idea that the best vision for the nation's forests was that of an agricultural crop, developed to produce only useful **species** and products. Pinchot, however, insisted that "The object of [conservationist] forest policy is not to preserve the forests because they are beautiful...or because they are refuges for the wild creatures of the wilderness...but the making of prosperous homes...Every other consideration is secondary." Because of its more moderate and politically palatable stance, conservation became, by the turn of the century, the more popular position. By 1905 conservation had become a blanket term for nearly all defense of the **environment**; the earlier distinction was lost until it began to re-emerge in the 1960s as "environmentalists" began once again to object to conservation's anthropocentric (human-centered) emphasis. More recently deep ecologists and bioregionalists have likewise departed from mainstream conservation, arguing that other species have intrinsic rights to exist outside of human interests.

Several factors led conservationist ideas to develop and spread when they did. By the end of the nineteenth century European settlement had reached across the entire North American continent. The census of 1890 declared the American frontier closed, a blow to the American myth of the virgin continent. Even more important, loggers, miners, settlers, and livestock herders were laying waste to the nation's forests, **grasslands**, and mountains from New York to California. The accelerating, and often highly wasteful, commercial exploitation of natural resources went almost completely unchecked as political corruption and the economic power of timber and lumber barons made regulation impossible. At the same time, the disappearance of American wildlife was starkly obvious. Within a generation the legendary flocks of passenger pigeons disappeared entirely, many of them shot for pig feed while they roosted. Millions of **bison** were slaughtered by market hunters for their skins and tongues or by sportsmen shooting from passing trains. Natural landmarks were equally threatened—Niagara Falls nearly lost its water to hydropower development, and California's Sequoia groves and Yosemite Valley were threatened by **logging** and grazing.

At the same time, post-Civil War scientific surveys were crossing the continent, identifying wildlife and forest resources. As a consequence of this data gathering, evidence became available to document the depletion of the continent's resources, which had long been assumed inexhaustible. Travellers and writers, including John Muir, Theodore Roosevelt, and Gifford Pinchot, had the opportunity to witness the alarming destruction and to raise public awareness and concern. Meanwhile an increasing proportion of the population had come to live in cities. These urbanites worked in occupations not directly dependent upon resource exploitation, and they were sympathetic to the idea of preserving public lands for recreational interests. From the beginning this urban population provided much of the support for the conservation movement.

As a scientific, humanistic, and progressive policy, conservation has led to a great variety of projects. The development of a professionally trained forest service to maintain national forests has limited the uncontrolled "tree mining" practiced by logging and railroad companies of the nineteenth century. Conservation-minded presidents and administrators have set aside millions of acres **public land** for national forests, parks, and other uses for the benefit of the public. A corps of professionally trained game managers and wildlife managers has developed to maintain game birds, fish, and mammals for public **recreation** on federal lands. (For much of its history, federal game conservation has involved extensive predator elimination programs, however

several decades of protest have led to more ecological approaches to game management in recent decades.) During the administration of Franklin D. Roosevelt, conservation projects included such economic development projects as the **Tennessee Valley Authority** (TVA), which dammed the Tennessee River for flood control and electricity generation. The Civilian Conservation Corps developed roads, built structures, and worked on **erosion** control projects for the public good. During this time the **Soil Conservation Service** was also set up to advise farmers in maintaining and developing their farmland.

At the same time, voluntary citizen conservation organizations have done extensive work to develop and maintain natural resources. The **Izaak Walton League**, **Ducks Unlimited**, and scores of local gun clubs and fishing groups have set up game sanctuaries, preserved **wetlands**, campaigned to control **water pollution**, and released young game birds and fish. Other organizations with less directly utilitarian objectives also worked in the name of conservation: the **National Audubon Society**, the **Sierra Club**, the **Wilderness Society**, **The Nature Conservancy**, and many other groups formed between 1895 and 1955 for the purpose of collective work and lobbying in defense of nature and wildlife.

An important aspect of conservation's growth has been the development of professional schools of forestry, game management, and **wildlife management**. When Gifford Pinchot began to study forestry, Yale had only meager resources and he gained the better part of his education at a French school of **forest management** in Nancy, France. Several decades later the Yale School of Forestry (financed largely by the wealthy Pinchot family) was able to produce such well-trained professionals as **Aldo Leopold**, who went on to develop the United States' first professional school of game management at the University of Wisconsin.

From the beginning, American conservation ideas, informed by the science of **ecology** and the practice of resource management on public lands, spread to other countries and regions. It is in recent decades, however, that the rhetoric of conservation has taken a prominent role in international development and affairs. The most visible international conservation organizations today is the United Nations Environment Program (UNEP), the Food and Agriculture Organization of the United Nations (FAO), and the **World Wildlife Fund**. In 1980 the International Union for the Conservation of Nature and Natural Resources (IUCN) published a document entitled the *World Conservation Strategy*, dedicated to helping individual states, and especially developing countries, plan for the maintenance and protection of **soil**, water, forests, and wildlife. A continuation and update of this theme appeared in 1987 with the publication of the UN World Commission on Environment and Development's paper, ***Our Common Future***. The idea of sustainable development, a goal of ecologically balanced, conservation-oriented economic development, was introduced in this 1987 paper and has since become a dominant ideal in international development programs of the 1990s.

Conservation biology

Conservation biology is concerned with the application of ecological and biological science to the conservation and protection of Earth's **biodiversity**. Conservation biology is a relatively recent field of scientific activity, having emerged during the past several decades in response to the accelerating biodiversity crisis. Conservation biology represents an integration of theory, basic and applied research, and broader educational goals. It includes much of **ecology** but extends it with social sciences, policy, and management.

The most important cause of the biodiversity crisis is the disturbance of natural habitats, particularly through the conversion of tropical forests into agricultural habitats. Biodiversity is also greatly threatened by the excessive **hunting** of certain **species**, by commercial forestry, by **climate** change, and by other stressors associated with human activities, such as air and **water pollution**. A central goal of conservation biology is to discover ways of avoiding or repairing the damages that human influences are causing to biodiversity. Important considerations include the development of science-based methods for conserving endangered populations of species on larger landscapes (or seascapes, in marine environments), and of designing systems of protected areas where natural ecosystems and indigenous species can be conserved.

Biodiversity and its importance

Biodiversity can be defined as the total richness of biological variation. The scope of biodiversity ranges from the genetic variation of individuals within and among populations of species, to the richness of species that co-occur in ecological communities. Some ecologists also consider

biodiversity to include the spatial and temporal changes of communities on the greater landscape or seascape.

About 1.7 million of Earth's species have been identified and given a scientific name. However, biologists have not yet "discovered" most species, especially those living in tropical habitats. According to some estimates, Earth may support as many as 30–50 million species, of which 90% occur in tropical ecosystems, particularly in old-growth rainforests. Biologists believe that most of the unknown species are invertebrates, especially species of beetles and other insects. Compared with invertebrates, the numbers of species of plants and vertebrate animals are relatively well known.

Biodiversity is valuable for many reasons, but these can be grouped into the following three classes:

(1) *Intrinsic value*. Regardless of its worth in terms of the needs of humans, biodiversity has its own, **intrinsic value**.

(2) *Utilitarian value*. Humans have an undeniable need to harvest wild and domesticated species and their communities as sources of food, materials, and energy. Although harvests of biodiversity can be conducted in ways that foster renewal, these potentially renewable resources are often harvested or managed too intensively, resulting in degradation or **extinction** of the resource.

(3) *Provision of ecological services*. Biodiversity provides numerous ecological services that are directly and indirectly important to human welfare. These services include biological productivity, **nutrient** cycling, cleansing of water and air, control of **erosion**, provision of atmospheric oxygen and removal of **carbon dioxide**, and other functions related to the health and integrity of ecosystems. According to the American biologist Peter Raven: "Biodiversity keeps the planet habitable and ecosystems functional."

Threats to biological diversity

Biodiversity at local, regional, continental, and global scales is critically threatened by human activities. The damages that are being caused to Earth's species and ecosystems are so severe that they are referred to by ecologists as a biodiversity crisis. Many permanent losses of biodiversity have already been caused by human influences, including the extinctions of numerous species and the losses of distinctive, natural communities. Unless there are substantial changes in the ways that humans affect ecosystems, there will be enormously greater losses of biodiversity in the near future.

Earth's natural biodiversity has always been subjected to extinction (that is, the permanent loss of species and other groups) The fossil record shows that species, families, and even entire phyla have appeared and disappeared on Earth. For example, many invertebrate phyla proliferated during an evolutionary radiation at the beginning of the Cambrian era about 570 million years ago, but most of these are now extinct.

Many of the natural extinctions occurred simultaneously, apparently as a result of an unpredictable catastrophe. For instance, about 65 million years ago a **mass extinction** occurred that resulted in the loss of the last of the dinosaurs and as many as 76% of the then-existing species. That catastrophe is believed to have been caused by a meteorite impacting Earth. In other cases, natural extinctions have been caused by more gradual environmental changes, for example in climate or in the intensity of disease or predation.

More recently, however, humans have been responsible for almost all of the extinctions that are occurring. In fact, species are now being lost so quickly that the changes represent a modern mass extinction. Well-known examples of extinctions caused by humans include the **dodo**, **passenger pigeon**, and great auk. Numerous other species have been taken to the brink of extinction, including the plains **bison**, **whooping crane**, **ivory-billed woodpecker**, and right whale. These losses have been caused by over-hunting and the disturbance and conversion of natural habitats.

In addition to these famous cases involving large animals, an even more ruinous damage to Earth's biodiversity is being caused by extensive losses of tropical ecosystems, particularly the conversion of tropical rain forests into agricultural habitats. Because tropical ecosystems are particularly rich in numbers of species, loss of natural tropical **habitat** causes extinctions of numerous species. Many of those species occurred nowhere else but in particular tropical locales.

The mission of conservation biology is to understand the causes and consequences of the modern crisis of extinction and degradation of Earth's biodiversity, and then to apply scientific principles to preventing or repairing the damages. This is largely done by conserving populations and by protecting natural areas.

Conservation at the population level

In some cases, **endangered species** can be enhanced by special programs that increase their breeding success and enhance the survival of their populations. Usually, a variety of actions is undertaken, along with the preservation of appropriate habitat, under a scheme that is known as a population recovery plan. Components of a population recovery plan may include such actions as (1) the careful monitoring of wild populations and the threats that they face; (2) research into the specific habitat needs of the endangered species; (3) the establishment of a captive-breeding program and the release of surplus individuals into the wild; (4) research into genetic variation within the species; and (5) other studies of basic biology and ecology that are considered necessary for preservation of the species, particularly in its natural habitats. Unfortunately, population recovery plans

have only been developed for a small fraction of endangered species, and most of these have been prepared for species that occur in relatively wealthy countries.

One example involves the whooping crane (*Grus americana*), an endangered species in North America. Because of excessive hunting and **critical habitat** loss, this species declined in abundance to the point where as few as only 15 individuals were alive in 1941. Since then, however, the wild population of whooping cranes has been vigorously protected in the United States and Canada, and their critical breeding, migratory, and wintering habitats have been preserved. In addition, the basic biology and behaviour of whooping cranes have been studied, and some wild birds have been taken into captivity and used in breeding programs to increase the total population of the species. Some of the captive-bred animals have been released to the wild, and whooping crane eggs have also been introduced into the nests of the closely related sandhill crane (*Grus canadensis*), which serve as foster parents. These applications of conservation biology have allowed the critically endangered population of whooping cranes to increase to more than 150 individuals in the mid-1980s, and to about 300 birds in 1997, of which about half were in captivity. Because of these actions, there is now guarded optimism for the survival of this endangered species.

Protected areas

Protected areas such as parks and ecological reserves are necessary for the conservation of biodiversity in wild, natural ecosystems. Most protected areas are established for the preservation of natural values, particularly the known habitats of endangered species, threatened ecological communities, or representative examples of widespread communities. However, many protected areas (particularly parks) are also used for human activities, as long as they do not severely threaten the ecological values that are being conserved. These uses can include **ecotourism**, and in some cases fishing, hunting, and even timber harvesting. In 1993 there were about 9,000 protected areas globally, with a total area of almost two million acres (792 million ha). Of this total, about 2,500 sites comprising 1.15 million acres (464 million ha) were fully protected, and could be considered to be ecological reserves.

Ideally, a national system of protected areas would provide for the longer-term conservation of all native species and their natural communities, including terrestrial, freshwater, and marine ecosystems. So far, however, no country has implemented a comprehensive system of ecological reserves to fully protect the natural biodiversity of the region. Moreover, many existing reserves are relatively small and are threatened by environmental changes and other disturbances, such as illegal hunting of animals and plants and sometimes intensive tourism.

Ecological knowledge has allowed conservation biologists to make important contributions to the optimized design of networks of protected areas. Important considerations include: (1) the need to protect areas that provide adequate representation of all types of natural ecosystems; (2) the need to preserve all endangered ecosystems and the habitats of threatened species; (3) the requirement of redundancy, so that if one example of an endangered **ecosystem** becomes lost through an unavoidable natural disturbance (such as a **hurricane** or **wildfire**), the type will continue to survive in another protected area; (4) the need to decide whether or not the network of protected areas should be linked by corridors, a matter of some controversy among ecologists.

Conservation biology has also made important contributions towards the spatial design of individual protected areas. Important considerations include (1) the need to make protected areas as large as possible, which will help to allow species and ecosystems to better cope with disturbances and environmental changes; (2) a preference for smaller reserves to have a minimal amount of edge, which helps to avoid damages that can be caused by certain predators and invasive species; (3) the need to take an ecosystem approach which ensues that the reserve and its surrounding area will be managed in an integrated manner.

Although conservation biology is a relatively young field, important progress is being made towards development of the effective ecological and biological tools necessary to preserve biodiversity.

Conservation design

see **Urban sprawl**

Conservation easements

A **conservation** easement is a covenant, restriction, or condition in a deed, will, or other legal document that allows the owner to maintain ownership and control of real property, but restricts the use of that property so the land is conserved in its natural state, or, in the case of a historic conservation easement, so that it provides a historic benefit.

The uses allowed by the easement can include **recreation**, agriculture, cultural uses, and establishment of **wildlife habitat**. The federal government allows tax deductions for conservation easements that provide a certified value to the public, such as protecting ecologically valuable natural habitat or, in the case of an easement based on the historical conservation of the property, that contribute to the historic character of the district in which the property is located. Conservation easements are legal instruments enabled by many states as well as non-United States governments, including Canada and most of its provinces.

[*Marie H. Bundy*]

Conservation International

Conservation International (CI) is a non-profit, private organization dedicated to saving the world's endangered rain forests and the plants and animals that rely on these habitats for survival. CI is basically a scientific organization, a fact which distinguishes it from other conservation groups. Its staff includes leading scientists in the fields of botany, ornithology, herpetology, marine biology, entomology, and zoology.

Founded in 1987 when it split off from **the Nature Conservancy**, CI now has over 55,000 members. The group, headed by Peter A. Seligmann, has gathered accolades since its inception. In 1991 *Outside Magazine* gave CI an A- (one of the two highest grades received) in its yearly report card rating 14 leading environmental groups.

The high praise is well founded. CI tends to successfully implement its many projects and goals. Many CI programs focus on building local capacity for conservation in developing countries through financial and technical support of local communities, private organizations, and government agencies. Their "ecosystem conservation" approach balances conservation goals with local economic needs. CI also funds and provides technical support to local communities, private organizations, and government agencies to help build sustainable economies while protecting **rain forest** ecosystems.

Four broad themes underlie all CI projects: 1) a focus on entire ecosystems; 2) integration of economic interests with ecological interests; 3) creation of a base of scientific knowledge necessary to make conservation-minded decisions; and 4) an effort to make it possible for conservation to be understood and implemented at the local level.

CI is involved with projects in 30 countries, including Botswana, Brazil, Canada, Colombia, Indonesia, Mexico, New Guinea, and the Philippines. In 2000, CI expanded into Cambodia and China, among others.

Among CI's many successful projects is the Rapid Assessment Program (RAP), which enlists the world's top field scientists to identify **wilderness** areas in need of urgent conservation attention. RAP teams have completed surveys in Bolivia, Ecuador, Belize, Peru, and Mexico, and CI plans at least 12 more surveys on four continents in the next three to five years. CI has also helped establish important **biosphere** reserves in rain forest countries. These efforts successfully demonstrate CI's **ecosystem** conservation approach, and prove that the economic needs of local communities can be reconciled with conservation needs. No harvesting or **hunting** is allowed in the reserves, but **buffer** zones, which include villages and towns, are located just outside the core areas.

CI strongly supports many educational programs. In 1988, it signed a long-term assistance agreement with Stanford University which involves exchange and training of Costa Rican students and resource managers. In 1989 CI began a program with the University of San Carlos which provides financial and technical support to the research activities in northern Guatemala of the university's Center for Conservation Studies. An educational program of a different kind, the Sorcerer's Apprentice, is designed to record ethnobotanical knowledge, protect useful **species**, and pass this information on to the next generation in indigenous communities. Young men and women in forestry services learn from traditional village healers and midwives.

In 2002, CI has already established several new ways to educate the people and help the **environment**, such as Centers for **Biodiversity** Conservation, the Global Conservation Fund, and a joint venture with Ford Motor Company called the Center for Environmental Leadership in Business. CI also focuses on activities in the major wilderness areas identified as the most endangered. The organization also has expanded its conservation efforts to new ecosystems, including marine, **desert**, and temperate rain forest regions.

Conservation Reserve Program

The Conservation Reserve Program (CRP) is a voluntary program for agricultural landowners, that encourages farmers to plant long-term resource-conserving vegetative ground cover to improve **soil** and water, and create more suitable **habitat** for fish and **wildlife**. Ground cover options include grasses, legumes, shrubs, and tree plantings. The program is authorized by the federal Food Security Act of 1985, as amended, and is implemented through the Commodity

Credit Corporation (CCC). It aims to promote good **land stewardship** and improve rural aesthetics.

The CRP offers annual rental payments, incentive payments, and cost-share assistance to establish approved cover on eligible cropland. The CCC provides assistance of as much as 50% of the landowner's cost in establishing an approved conservation program. Contracts remain in effect for between 10 and 15 years. Annual rental payments are based on the agriculture rental value of the land used in the program. The program provides needed income support for farmers, and helps to curb production of surplus commodities.

Eligibility for participation in CRP extends to individuals, partnerships, associations, Indian tribal ventures corporations, estates, trusts, other business enterprises or legal entities. States, political subdivisions of states, or agencies thereof owning or operating croplands, may also apply.

The CCC via the Farm Service Agency (FSA) manages the CRP. The Natural Resources Conservation Service (NRCS) and the Cooperative State Research and Education Extension Service provide support. State forestry agencies and local soil and **water conservation** districts also provide assistance.

To be eligible for the CRP, cropland should have been planted or considered planted to an agricultural commodity in two of the five most recent crop years. Eligibility encompasses highly **erodible** acreage, cropped **wetlands**, and land surrounding non-cropped wetlands. The cropland must be owned or operated for at least 12 months before the close of the sign-up period. Exceptions can be made for land that was acquired by will or **succession**, or if the FSA determines that ownership was not acquired for the purpose of placing the land in the conservation reserve.

Initially, **erosion** reduction was the sole criterion for acceptance in the CRP, and in 1986–87, 22 million acres (8.9 million ha) were enrolled for this purpose. CRP proved to be effective. According NRCS **statistics**, average erosion on enrolled acres declined by about 90%. It was estimated that the program reduced overall erosion nationwide by more than 22% even though less than 10% of the nation's cropland was enrolled.

An Environmental Benefits Index (EBI) is used to prioritize applications for the CRP. EBI factors include: Wildlife habitat benefits, **water quality** benefits from reduced erosion, **runoff**, and **leaching**, and **air quality** benefits from reduced wind erosion. The NRCS collects data for each of the factors and, based on its analysis, applications are ranked. Selections are made from that ranking.

The CCC bases rental rates on the productivity of soils within a county, and the average rent for the past three years of local agricultural land. The maximum CRP rental rate for each applicant is calculated in advance of enrollment. Applicants may accept that rate, or may offer a lower rental rate to increase the likelihood that their project will be funded.

The CCC encourages restoration of wetlands by providing a 25% incentive payment of the costs involved to establish approved cover. This is in addition to the normal 50% cost share for non-wetlands. Eligible acreage devoted to special conservation practices, such as riparian buffers, filter strips, grassed waterways, shelter belts, living snow fences, contour grass strips, salt tolerant vegetation, and shallow water areas for wildlife, may be enrolled at any time and is not subject to competitive bidding.

When CRP contracts expire, participants must continue to follow approved conservation plans. They must comply with wetland, **endangered species** and other federal, state, and local environmental laws, and they must respect any continuing conservation easement on the property.

The United States Department of Agriculture (USDA) provides information and technical assistance to CRP participants who wish to return CRP land to row-crop producing status as their contracts expire. This is to ensure that the land is developed in a sound, productive, and sustainable manner, preventing excessive erosion, protecting water quality, and employing other measures that enhance soil moisture-retaining ability.

In states such as North Dakota, the landscape has been changed dramatically since the introduction of the CRP. In the 1970s and early 1980s, fields with steep hills and areas of light soil were often cultivated from fencerow-to-fencerow. The result often was severe erosion and permanent loss of soil fertility. In some areas, winters were dominated by "snirtstorms" when a combination of dirt and snow blew across the landscape depositing a dark coating on countryside downwind. In contrast, today's travelers find these landscapes covered with green vegetation in summer and white snow in winter.

The CRP has particularly benefited migratory birds in states such as North Dakota, South Dakota, and Montana. The perennial vegetation on marginal farmland has provided refuge for migrating birds, and added breeding habitat for others. North Dakota farmers have enrolled about 10% of the state's cropland in the CRP.

The fiscal year 2000 federal agricultural appropriations bill authorized a pilot project of harvesting of **biomass** from CRP land to be used for energy production. Six projects were authorized, no more than one of which could be in any state. Vegetation could not be harvested more often than once every two years, and no commercial use could be made of the harvested biomass other than energy production. Annual CRP rental payments are reduced by twenty five percent during the year the acreage is harvested. Land that is devoted

to field windbreaks, waterways, shallow water ways for wildlife, contour grass strips, shelter belts, living snow fences, permanent vegetation to reduce **salinity**, salt tolerant vegetative cover, filter strips, riparian buffers, wetland restoration, and cross-wind trap strips is not eligible for this program. By 2002, contracts had been approved in Iowa, Illinois, Oklahoma, Minnesota, New York, and Pennsylvania.

In June of 2001, the USDA announced a six-state pilot program as part of the CRP to restore up to 500,000 acres (202,000 ha) of farmable wetlands and associated buffers. The Farmable Wetlands Pilot Program is intended to help producers improve the **hydrology** and vegetation of eligible land in Iowa, Minnesota, Montana, Nebraska, North Dakota, and South Dakota. Restoring wetlands in these states should reduce downstream flood damage, improve surface and **groundwater** quality, and recharge groundwater supplies. Essential habitat for migratory birds and many other wildlife **species**, including threatened and endangered species will be created and enhanced. Recreational activities such as hiking and bird watching will also be improved.

In 1985, the year in which CRP originated, spring surveys by the U.S **Fish and Wildlife Service** estimated waterfowl breeding populations at 25.6 million ducks. A fall flight of 54.5 million was predicted. Several species of ducks including mallards, pintails, and blue-winged teal appeared to be fading away. Numbers were at or near their lowest ebb in 30 years. Between 1986 and 1990, farmers enrolled 8.2 million acres (3.3 million hectare) of cropland in CRP within an area known as the **prairie** pothole region. This large glaciated area of the north central United States and southern Canada is where up to 70% of North America's ducks are hatched. Through CRP, nearly 13,000 mi^2 (34,000 km^2) was converted to superior nesting habitat through CRP.

In the early 1990s, increased precipitation filled the prairie potholes and many waterfowl ended their spring **migration** on CRP land, rather than continuing migration to their usual breeding grounds in Canada. Nesting densities increased many fold. Potholes surrounded by CRP grass provided more secure habitat for nests, and hatchlings were no longer easy targets for predators. Nesting success tripled, from 10 to 30%, and waterfowl **mortality** no longer exceeded annual additions. By 1995, ten years after the start of CRP, 36.9 million ducks were included in the annual spring survey numbers, a 40% increase in 10 years.

Waterfowl are not the only bird species to benefit from CRP. In one study, breeding birds were counted in about 400 fields in eastern Montana, North and South Dakota, and western Minnesota. These states have nearly 30% of all land included in the CRP. Fields were planted mostly to mixtures of native and introduced grasses and legumes. For most of the seventy-three different species counted, numbers were far higher in CRP fields than in cropland. Differences were greatest for several grassland species whose numbers had been markedly declining in recent surveys. Two species, lark buntings (*Calamospiza melanocorys*) and grasshopper sparrows (*Ammodramus savannarum*), were 10 and 16 times more common in CRP **environment** than in cropland. The investigators concluded that restoration of suitable habitat in the form of introduced grasses and legumes can have an enormous beneficial effect on populations of grassland birds.

When CRP was due to expire in 1995, restoration of prairie pothole breeding grounds was in jeopardy. United States farm policy was undergoing major change and it appeared that the CRP would not be continued. **Ducks Unlimited** and other wildlife organizations lobbied heavily, and funding of one billion dollars was included in the 1996 Farm Bill to continue the program for another seven years. Moreover, the guidelines for the continuing program were geared more directly to the preservation of wetlands and waterfowl conservation. The prairie pothole region was designated a national conservation priority area, and during the March 1997 sign-up more acres in the prairie pothole region were enrolled in CRP than were due to expire.

In its first 10 years, the CRP cost nearly $2 billion per year. Opponents have argued that this is too expensive, while proponents maintain that the costs are offset by its conservation and environmental benefits. Estimates of the annual value of benefits range from slightly less than $1 billion to more than $1.5 billion. Some analysts claim that the value of benefits approaches or exceeds costs in some sites.

The USDA announced that there would not be general CRP signup for Fiscal Year 2002 although producers could continue to enroll acreage eligible under continuous enrollment provisions. Later, they announced that CRP contracts expiring in 2002 could be extended for another year.

Conservation tillage

Conservation tillage is any **tilth** sequence that reduces loss of **soil** or water in farmland. It is often a form of non-inversion tillage that retains significant amounts of plant residues on the surface. Thirty percent of the soil surface must be covered with plant residues at crop planting time to qualify as conservation tillage under the Conservation Technology Information Center definition. Other forms of conservation tillage include ridge tillage, rough plowing, and tillage that incorporates plant residues in the top few inches of soil.

A number of implements for primary tillage are used to retain all or a part of the residues from the previous crop on the soil surface. These include machines that fracture the soil, such as chisel plows, combination chisel plows, disk harrows, field cultivators, undercutters, and strip tillage machines. In a no-till system, the soil is not disturbed before planting. Most tillage systems that employ the moldboard plow are not considered conservation tillage because the moldboard plow leaves only a small amount of residue on the soil surface (0–10%).

When compared with conventional tillage (moldboard plow with no residue on the surface), various benefits from conservation tillage have been reported. Chief among the benefits are reduced wind and water **erosion** and improved **water conservation**. Erosion reductions from 50–90% as compared with conventional tillage are common. Conservation tillage often relies on herbicides to help control weeds and may require little or no post-planting cultivation for control of weeds in row crops. Depending on the management system used, **herbicide** amounts may or may not be greater than the amounts used on conventionally tilled land. Yields from conservation tillage, particularly corn, may be greater or smaller than from conventional tilled soil. Crop yield problems are most frequent on wet soils in the northern United States. Costs of tillage may be lower, but not always, from conservation tillage as compared with conventional.

Consultative Group on International Agricultural Research

The Consultative Group on International Agricultural Research (CGIAR) was founded in 1971 to improve food production in developing countries. Research into agricultural productivity and the management of **natural resources** are the two goals of this organization, and it is dedicated to making the scientific advances of industrialized nations available to poorer countries. The CGIAR emphasizes the importance of developing sustainable increases in agricultural yields and creating technologies that can be used by farmers with limited financial resources.

Membership consists of governments, private foundations, and international and regional organizations. The goals of this association are carried out by a network of International Agricultural Research Centers (IARCs). There are currently 18 such centers throughout the world, all but four of them in developing countries, and they are each legally distinct entities, over which the CGIAR has no direct authority. The group has no constitution or by-laws, and decisions are reached by consensus after consultations with its members, either informally or at their semiannual meetings. The function of the CGIAR is to assist and advise the IARCs, and to this end it maintains a Technical Advisory Committee (TAC) of scientists who review ongoing research programs at each center.

Each IARC has its own board of trustees as well as its own management, and they formulate individual research programs. The research centers pursue different goals, addressing problems in a particular sector of agriculture, such as livestock production or agricultural challenges in specific parts of the world, such as crop production in the semi-arid regions of Africa and Asia. Some centers conduct research into integrated plant protection, and others into forestry, while some are more concerned with policy issues, such as food distribution and the international food trade. One of the priorities of the CGIAR is the **conservation** of seed and plant material, known as germplasm, and the development of policies and programs to ensure that these resources are available and fully utilized in developing countries. The International Board for Plant Genetic Resources is devoted exclusively to this goal. Besides research, the basic function of the IARCs is educational, and in the past two decades over 45,000 scientists have been trained in the CGIAR system.

The central challenge facing the CGIAR is world **population growth** and the need to increase agricultural production by nearly 50% in the next 20 years while preserving natural resources. The group was one of the main contributors to the so-called "Green Revolution." It helped develop new high-yielding varieties of cereals and introduced

them into countries previously unable to grow the food; some of these countries now have agricultural surpluses. In 2001, CGIAR in South Africa worked on developing two new types of maize, which have a 30–50% larger crop than what is currently being produced by the smaller farmers. The CGIAR is working to increase production even further, narrowing the gap between actual and potential yields, while continuing its efforts to limit **soil erosion**, **desertification**, and other kinds of **environmental degradation**.

The **World Bank**, the Food and Agriculture Organization (FAO) and the United Nations Development Program (UNDP) are among the original sponsors of the CGIAR, and the organization has its headquarters at the offices of the World Bank, which also funds central staffing positions. Combined funding has grown from $15 million in 1971 to over $340 million in 1999, and the CGIAR has a staff of 12,000 worldwide. The group publishes a newsletter called *CGIAR Highlights*.

Container deposit legislation

Container deposit legislation requires payment of a deposit on the sale of most or all beverage containers and may require that a certain%age of beverage containers be allocated for refillables. The legislation shifts the costs of collecting and processing beverage containers from local governments and taxpayers to manufacturers, retailers and consumers.

While laws vary from state to state, even city to city, container deposit legislation generally provides a monetary incentive for returning beverage cans and bottles for **recycling**. Distributors and bottlers are required to collect a deposit from the retailer on each can and bottle sold. The retailer collects the deposit from consumers, reimbursing the consumer when the container is returned to the store. The retailer then collects the deposit from the distributor or bottler, completing the cycle. Consumers who choose not to return their cans and bottles lose their deposit, which usually becomes the property of the distributors and bottlers, though in some states, unredeemed deposits are collected by the state.

Oregon implemented the first deposit law or "bottle bill" in 1972. In the 1970s and 1980s, industry opponents fought container deposit laws on the grounds that they would result in a loss of jobs, an increase in prices, and a reduction in sales. Now opponents denounce the legislation as being detrimental to curbside recycling programs. But over the past two decades, container deposit legislation has proven effective not only in controlling litter and conserving **natural resources** but in reducing the **waste stream** as well.

Recovery rates for beverage containers covered under the deposit system depend on the amount of deposit and the size of the container. The overall recovery rate for beverage containers ranges from 75 to 93%. The reduction in container litter after implementation of the deposit law ranges from 42 to 86%, and reduction in total volume ranges from 30 to 60%. Although beverage containers make up just over 5% by weight of all **municipal solid waste** generated in the United States, they account for nearly 10% of all waste recovered, according to the **Environmental Protection Agency** (EPA). While the cans and bottles that are recycled into new containers or new products ease the burden on the **environment**, recycling is a second-best solution.

As recently as 1960, 95% of all soft drinks and 53% of all packaged beer was sold in refillable glass bottles. Those bottles required a deposit and were returned for **reuse** 20 or more times. But the centralization of the beverage industry, the increased mobility of consumers, and the desire for convenience resulted in the virtual disappearance of the reusable beverage container. Today, refillables make up less than 6% by volume of packaged soft drinks and 5% by volume of packaged beer, and these percentages shrink every year, according to the National Soft Drink Association and the Beer Institute.

Reuse is a more environmentally responsible **waste management** option, and is superior to recycling in the **waste reduction** hierarchy established by the EPA. While the container industry has been unwilling to promote refillable bottles, new interest in container deposit legislation may move industries and governments to adopt reuse as part of their waste management practices.

Industry-funded studies have found that a refillable glass bottle used as few as eight times consumes less energy than any other container, including recycled containers. A study conducted for the National Association for Plastic Container Recovery found that the 16-oz (1 pt) refillable bottle produces the least amount of waterborne waste and fewest atmospheric emissions of all container types.

To date, 10 states and one city have enacted beverage container deposit systems, designed to collect and process beverage bottles and cans. A deposit of 5–10 cents per can or bottle is an economic incentive to return the container. The states that have some form of container deposit legislation and accompanying deposit system include Oregon, New York, Connecticut, Maine, Iowa, Vermont, Michigan, Massachusetts, Delaware, and California. Legislation is pending in 25 state legislatures, and on **Earth Day** 1993, a national

bottle bill was introduced in the U.S. Congress by sponsors from the House of Representatives.

Despite the fact that opinion polls show the public supports bottle bills by a nearly three-to-one margin, for two decades the beverage and packaging industries have successfully blocked the passage of bottle bills in nearly 40 states and even the most successful container deposit programs have come under attack and are threatened with repeal.

Connecticut has one of the highest percentages of refillable beer bottles in the nation, according to **statistics** from the Beer Institute. Despite the success of the state's five-cents-per-container deposit legislation, Governor Lowell Weicker Jr. has pushed for repeal of the legislation, to be replaced by a five-cents-per-container tax to benefit the state parks system. Opponents to Weicker's plan insist that the repeal of the deposit law would result in greater numbers of bottles and cans left strewn across the state.

Others predict the repeal of the bottle bill would impact the state in other ways: about 1,000 jobs would be lost; small redemption centers would go out of business; and recycling rates for glass, **aluminum** and plastic would drop. In addition, it has been estimated that repeal would cost municipal curbside recycling programs in Connecticut between $5.4 and $12.5 million annually.

The United States has a long way to go to catch up to progressive countries such as Sweden, which does not allow aluminum cans to be manufactured or sold without industry assurances of a 75% recycling rate. Concerned that voluntary recycling would not meet these standards, the beverage, packaging and retail industries in Sweden have devised a deposit-refund system to collect used aluminum cans. Consumers in Sweden return their aluminum cans at a rate that has not been achieved in any other country. The 75% recycling rate was achieved in 1987, and industry experts expect the rate to exceed 86% in 1993. Most North American deposit systems rely on the distributor or bottler, but the deposit in Sweden originates with the can manufacturer or drink importer delivering cans within the country. Also, retail participation is voluntary: retailers collect the deposit but are not required to redeem the containers, though most do.

In 1991, 122 billion containers, weighing about 7.2 million tons, were produced in the United States—a 100% increase in packaging waste since 1960. Containers and packaging are the single largest component of the waste stream and they offer the greatest potential for reduction, reuse, and recycling, according to the EPA. Where individuals, industries, and governments will not voluntarily comply with recycling programs, container deposit legislation has decreased the amount of **recyclables** entering the waste stream.

Contaminated soil

The presence of pollutants in soils at concentrations above background levels that pose a potential health or ecological risk. Soils can be contaminated by many human actions including the **discharge** of solids and liquid pollutants at the **soil** surface; **pesticide** application; subsurface releases from leaks in buried tanks, pipes, and landfills; and deposition of atmospheric contaminants such as dusts and particles containing **lead**. Common contaminants include volatile hydrocarbons—such as **benzene**, **toluene**, ethylene, and **xylene** (BTEX compounds)—found in fuels; heavy paraffins and chlorinated organic compounds such as polychlorinated biphenyl (PCB) and **pentachlorophenol** (PCP); inorganic compounds such as lead, **cadmium**, **arsenic** and **mercury**; and **radionuclides** such as tritium. Often, soil is contaminated with a mixture of contaminants. The nature of soil, the contaminant's chemical and physical characteristics, and environmental factors such as **climate** and **hydrology** interact to determine the accumulation, mobility, toxicity, and overall significance of the contaminant in any specific instance.

Fate of soil contaminants

Contaminants in soils may be present in solid, liquid, and gaseous phases. When liquids are released, they move downward through the soil. Some may fill pore spaces as liquids, some may partition or sorb onto mineral soil surfaces, some may dissolve into water in the soft pores, and some may volatilize. For most **hydrocarbons**, a multiphase system is common. When contaminants reach the **water table** (where the voids between soil particles are completely filled with water), contaminant behavior depends on its density. Light BTEX-type compounds float on the water table while dense chlorinated compounds may sink. While many hydrocarbon compounds are not very soluble, even low levels of dissolved

contaminants may produce unsafe or unacceptable **groundwater** quality. Other contaminants such as inorganic salts, such as **nitrates**, may be highly soluble and move rapidly through the **environment**. Metals demonstrate a range of behaviors. Some may be chemically bound and thus quite immobile; some may dissolve and be transported by groundwater and **infiltration**.

Contaminated pore water, called leachate, may be transported in the groundwater flow. Groundwater travels both horizontally and vertically. A portion of the contaminant, called residual, is often left behind as the flow passes, thus contaminating soils after the major contaminant **plume** has passed. If the groundwater velocity is fast, for example, hundreds of feet per year, the zone of contamination may spread quickly, potentially contaminating extraction **wells** or other resources. Over years or decades, especially in sandy or porous soils, groundwater contaminants and leachate may be transported over distances of miles, producing a situation that is very difficult and expensive to remedy. In these cases, immediate action is needed to contain and clean up the contamination. In cases where soils are largely comprised of fine-grained silts and clays, contaminants may spread very slowly. Such examples show the importance of site-specific factors in evaluating the significance of soil contamination as well as the selection of a cleanup strategy.

Superfund and other legislation

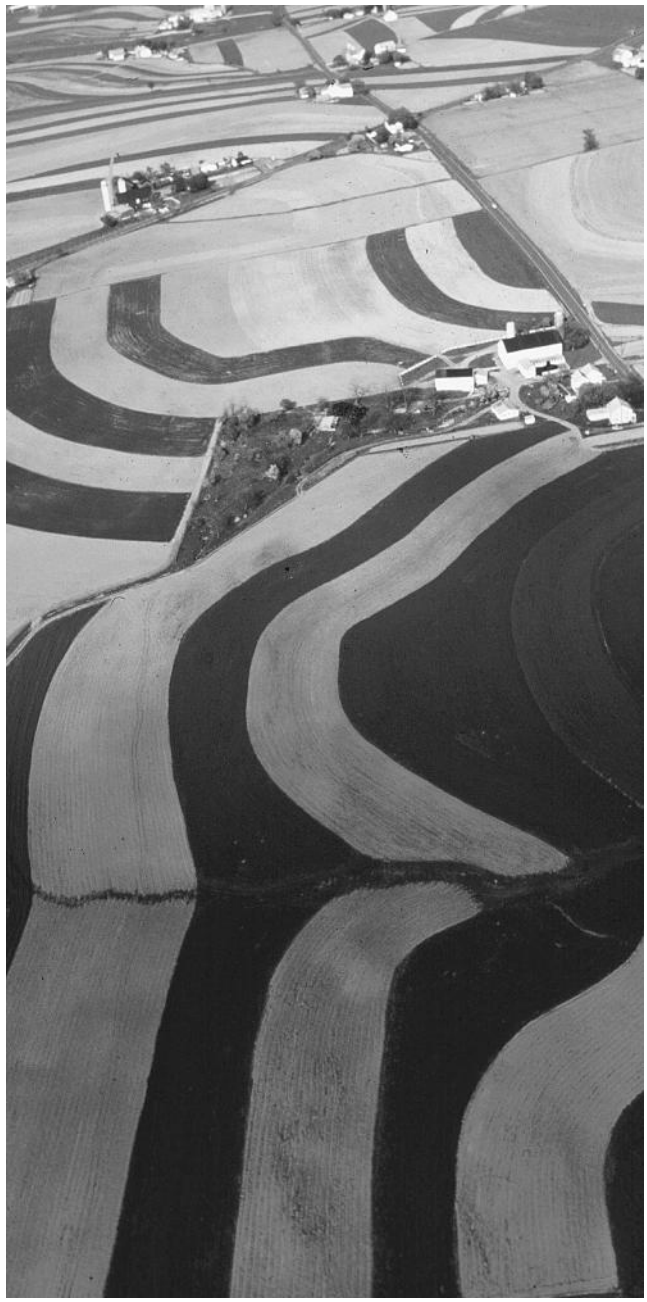
Prior to the 1970s, inappropriate land disposal practices, such as dumping untreated liquids in lagoons and landfills, were common and widespread. The presence and potential impacts of soil contamination were brought to public attention after well-publicized incidents at **Love Canal**, New York and the Valley of the Drums. Congress responded by passing the **Comprehensive Environmental Response, Compensation, and Liability Act** in 1980 (commonly known as CERCLA or Superfund) to provide funds with which to cleanup the worst sites. After five years of much litigation but little action, Congress updated this law in 1986 with the Superfund Amendments and Reauthorization Act. At present, about 1,200 sites across the United States have been selected as **National Priorities List** (NPL) sites and are eligible under CERCLA for federal assistance for cleanup. These Superfund sites tend to be the nation's largest and worst sites in terms of the possibility for adverse human and environmental impacts and the most expensive ones to clean up. While not as well recognized, numerous other sites have serious soil contamination problems. The U.S. Office of Technology Assessment and **Environmental Protection Agency** (EPA) estimate that about 20,000 abandoned waste sites and 600,000 other sites of land contamination exist in the United States. These estimates exclude soils contaminated with lead in older city areas, the accumulation of fertilizers, pesticides, and insecticides in agricultural lands, and other classes of potentially significant soil contamination. Federal and state programs address only some of these sites. Currently, CERCLA is the EPA's largest program, with expenditures exceeding three billion dollars over the last 15 years. However, this is only a fraction of the cost to government and industry that will be needed to cleanup all waste sites. Typical estimates of funds required to mitigate the worst 9,000 waste sites reach at least $500 billion; a 50-year time period is anticipated. The problem of contaminated soil is significant not only in the United States but in all industrialized countries.

U.S. laws such as CERCLA and the **Resource Conservation and Recovery Act** (RCRA) attempt to prohibit practices that have led to extensive soil contamination in the past. These laws restrict disposal practices; mandate financial liability to recover cleanup costs (as well as personal injury and property damage) and criminal liability to discourage willful misconduct or negligence; require record keeping to track waste; and provide incentives to reduce waste generation and improve **waste management**.

Soil cleanups

The cleanup or **remediation** of contaminated soils takes two major approaches: source control and containment, or soil and residual treatment and management. Typical containment approaches include caps and covers over the waste in order to limit infiltration of rain and snow melt and thus decrease the leachate from the contaminated soils. Horizontal transport in near-surface soils and groundwater may be controlled by vertical **slurry** walls. Clay, cement, or synthetic membranes may be used to encapsulate soil contaminants. Contaminated water and leachate may be hydraulically isolated and managed with groundwater pump-and-treat systems, sometimes coupled with the injection of clean water to control the spread of contaminants. Such containment approaches only reduce the mobility of the contaminant, and the barriers used to isolate the waste must be maintained indefinitely.

The second approach treats the soil to reduce the toxicity and volume of contaminants. These approaches may be broken down into extractive and *in situ* methods. Extractive options involve the removal of contaminated soil, generally for treatment and disposal in an appropriate **landfill** or for **incineration** where contaminants are broken down by thermal oxidation. *In situ* processes treat the soil in-place. *In situ* options include thermal, biological, and separation/extraction technologies. Thermal technologies include thermal desorption and in-place vitrification (glassification). Biological treatment includes biodegradation by soil **fungi** and bacteria that ultimately renders contaminants into **carbon dioxide** and water. This process is called mineralization. Biodegradation may produce long-lived toxic intermediate products. Separation technologies include soil vapor extrac-



tion for volatile organic compounds that removes a fraction of the contaminants by enhancing volatilization by an induced subsurface air flow; stabilization or chemical fixation that uses additives to bind organics and **heavy metals**, thus eliminating contaminated leachate; soil washing and flushing using dispersants, solvents, or other means to solubilize certain contaminants such as PCBs and enhance their removal; and finally, groundwater pump and treat schemes that purge the contaminated soils with clean water in a flushing action. The contaminated groundwater may then be treated by air stripping, steam stripping, **carbon absorption**, precipitation and flocculation and contaminant removal by **ion exchange**. A number of these approaches—*in situ* soil vitrification and enhanced **bioremediation** using engineered microorganisms—are experimental.

The number of potential remediation options is large and expanding due to an active research program that is driven by the need for low cost and more effective solutions. The selection of an appropriate cleanup strategy for contaminated soils requires a thorough characterization of the site and an analysis of the cost-effectiveness of suitable containment and treatment options. A site-specific analysis is required since the distribution and treatment of wastes may be complicated by variation in geology, hydrology, waste characteristics, and other factors at the site. Often, a demonstration of the effectiveness of an innovative or experimental approach may be required by governmental authorities prior to full scale implementation. In general, large sites use a combination of remediation options. Pump and treat and vapor extraction are the most popular technologies.

Cleanup costs and cleanup standards

The cleanup of contaminated soils can involve significant expense and risk. In general, *in situ* containment is cheaper than soil treatment, at least in the short run. While the Superfund law establishes a preference for permanent remedies, many cleanups that have been funded under this law have used both containment and treatment options. In general, *in situ* treatment methods such as groundwater pump and treat are less expensive than extractive approaches such as soil incineration. *In situ* options, however, may not achieve cleanup goals. Like other processes, costs increase with higher removal levels. Excavation and incineration of contaminated soil can cost $1,500 per ton, leading to total costs of many millions of dollars at large sites. Superfund cleanups have averaged about $26 million (however, a substantial fraction of this is for site investigations). In contrast, small fuel spills at **gasoline** stations may be mitigated using vapor extraction at costs under $50,000.

Unlike air and water, which have specific federal laws and regulations detailing maximum allowable levels of contaminants, no levels have been set for contaminants in soils. Instead, the Environmental Protection Agency and states use several approaches to set specific acceptable contaminant levels. For Superfund sites, cleanup standards must exceed applicable or relevant and appropriate requirements (ARARs) under federal environmental and public health laws. More generally, cleanup standards may be based on achieving

A contour farm in southeastern Pennsylvania. (Photograph by Jerry Irwin. Photo Researchers Inc. Reproduced by permission.)

background levels, that is, the concentrations found in similar, nearby, and unpolluted soils. Second, soil contaminant levels may be acceptable if the soil does not produce leachate with concentration levels above drinking water standards. Such determinations are often based on a test called the Toxics Characteristic Leaching Procedure which mildly acidifies and agitates the soil. Contaminant levels in the leachate below the maximum contaminant levels (MCLs) in the federal **Safe Drinking Water Act** are acceptable. Third, soil contaminant levels may be set in a determination of health risks based on typical or worst case exposures. Exposures can include inhalation of soils as dust, ingestion of soil (generally by children), and direct skin contact with soil. In part, these various approaches response to the complexity of contaminant mobility and toxicity in soils and the difficulty of pinning down acceptable and safe levels.

Convention on International Trade in Endangered Species of Wild Fauna and Flora (1975)

The Convention on International Trade in **Endangered Species** of Wild **Fauna** and Flora (CITES), was signed in 1973 and came into force in 1975. The aim of the treaty is to prevent international trade in listed endangered or threatened animal and plant **species** and products made from them. A full-time, paid secretariat to administer the treaty was initially funded by the United Nations Environmental Program, but has since been funded by the parties to the treaty. By 2002, 158 nations had become party to CITES, including most of the major **wildlife** trading nations, making CITES the most widely accepted wildlife **conservation** agreement in the world. The parties to the treaty meet every two years to evaluate and amend the treaty if necessary.

The species covered by the treaty are listed in three appendices, each of which requires different trade restrictions. Appendix I applies to "all species threatened with extinction," such as African and Asian **elephants** (*Loxodonta africana* and *Elephas maximus*, the hyacinth macaw (*Anodorhynchus hyacinthinus*), and Queen Alexandria's birdwing butterfly (*Ornithoptera alexandrae*). Commercial trade is generally prohibited for the over 900 listed species. Appendix II applies to "all species which although not necessarily now threatened with **extinction** may become so unless trade in specimens of such species is subject to strict regulation," such as the polar bear, giant clams, and Pacific Coast mahogany. Trade in these species requires an export permit from the country of origin. Currently, over 4,000 animals and 22,000 plants (mainly orchids) are listed in Appendix II. Appendix III is designed to help individual nations control the trade of any species. Any species may be listed in Appendix III for any nation. Once listed, any export of this species from the listing country requires an export permit. Usually a species listed in Appendix III is protected within that nation's borders. These trade restrictions apply only to signatory nations, and only to trade between countries, not to practices within countries.

CITES relies on signatory nations to pass domestic laws to carry out the principles included in the treaty. In the United States, the **Endangered Species Act** and the Lacey Act include domestic requirements to implement CITES, and the **Fish and Wildlife Service** is the chief enforcement agency. In other nations, if and when such legislation is passed, effective implementation of these domestic laws is required. This is perhaps the most problematic aspect of CITES, since most signatory nations have poor administrative capacity, even if they have strong desire for enforcement. This is especially a problem in poorer nations of the world, where monies for regulation of trade in endangered species is forced down the agenda by more pressing social and economic issues.

CITES can be regarded as moderately successful. There has been steady progress toward compliance with the treaty, though tremendous enforcement problems still exist. Due to the international scope and size of world wildlife trade, enforcement of CITES is estimated to be only 60–65% effective worldwide. International trade in endangered species is still big business; the profits from such trade can be huge. In 1988, the world market for **exotic species** was

estimated to be $5 billion, $1.5 billion of which was estimated to be illegal. Among the most lucrative products traded are reptile skins, fur coats, and ingredients for traditional drugs. If violations are discovered, the goods are confiscated and penalties and fines for the violators are established by each country. Occasionally, sanctions are imposed on a nation if it flagrantly violates the convention.

Convention on Long-Range Transboundary Air Pollution (1979)

Held in Geneva in 1979 under the auspices of the United Nations, the goal of the Convention on Long-Range Transboundary **Air Pollution** was to reduce air **pollution** and **acid rain**, particularly in Europe and North America. The accord went into effect in March 1983. It was signed by the United States and Canada, as well as European countries, and the signatories agreed to cooperate in researching and monitoring air pollution and to exchange information on developing technologies for **air pollution control**. This convention established the Cooperative Programme for Monitoring and Evaluating of the Long-Range Transmission of Air Pollutants in Europe, which was first funded in 1984. The countries that signed the treaty also agreed to reduce their sulfur emissions 30% by 1993. All of the countries were able to meet this goal, with many coutries reducing more than 50–60% of their emissions.

Convention on the Conservation of Migratory Species of Wild Animals (1979)

The first attempt at a global approach to **wildlife management**, the Convention on the **Conservation** of Migratory **Species** of Wild Animals was held in Bonn, Germany in 1979. The purpose of the convention was to reach an agreement on the management of wild animals that migrate "cyclically and predictably" across international boundaries. Egypt, Italy, the United Kingdom, Denmark, and Sweden, among other nations, signed an accord on this issue; the treaty went into effect in 1983, but the United States and Canada, as well as the former Soviet Union, still have not agreed to it.

The challenge facing the convention was how to assist nations that did not have **wildlife** management programs while not disrupting those that had already established them. The United States and Canada did not believe that the agreement reached in Bonn met this challenge. Representatives from both countries argued that the definition of a migratory animal was too broad; it would embrace nearly every game bird or animal in North America, including rabbits, deer, and bear. But both countries were particularly concerned that the agreement did not sufficiently honor national sovereignty, and they believed it threatened the effectiveness of the federal-state and federal-provincial systems that were already in place.

It is widely believed that the principal failure of this convention was its inability to find language dealing with federalist systems that was acceptable to all. The agreement also came into conflict with other laws, particularly laws governing national jurisdictions and territorial boundaries at sea, but it is still considered an important advance in the process of developing international environmental agreements. *See also* Environmental law

Convention on the Law of the Sea (1982)

During the age of exploration in the seventeenth century, the Dutch lawyer Hugo Grotius formulated the legal princi-

ple that the ocean was free (*Mare liberum*), which became the basis of the law of the sea. During the eighteenth century, each coastal nation was granted sovereignty over an offshore margin of three nautical miles to provide for better defense against pirates and other intruders. As undersea exploration advanced in the twentieth century, nations became increasingly interested in the potential resources of the oceans. By the 1970s, many were determined to exploit resources such as **petroleum** on the continental shelf and manganese nodules rich with metals on the deep ocean floor, but uncertainties about the legal status of these resources inhibited investment.

In 1974 the United Nations responded to these concerns and convened a Conference on the Law of the Sea, at which the nations of the world negotiated a consensus dividing the ocean among them. The participants drafted a proposed constitution for the world's oceans, including in it a number of provisions that radically altered their legal status. First, the convention extended the **territorial sea** from three to 22 nautical miles, giving nations the same rights and responsibilities within this zone that they possess over land. Negotiations were necessary to ensure that ships have a right to navigate these coastal zones when going from one ocean to another.

The convention also acknowledged a 200 nautical mile **Exclusive Economic Zone** (EEZ), in which nations could regulate fisheries as well as resource exploration and exploitation. By the late 1970s, over 100 nations had already claimed territorial seas extending from 12 to 200 miles. The United States, for example, claims a 200 mile zone. Today, EEZs cover about one third of the ocean, completely dividing the North Sea, the **Mediterranean Sea**, the Gulf of Mexico, and the Caribbean among coastal states. They also encompass an area that yields more than 90% of the ocean's fish catch, and they are considered a potentially effective means to control **overfishing** because they provide governments clear responsibility for their own fisheries.

The most heated debates during the convention, however, did not concern the EEZs, but involved provisions concerning seabed mining. **Third World** nations insisted that deep-sea metals were the common heritage of mankind, and that their wealth should be shared. After fierce disagreements, a compromise was reached in 1980 that would establish a new International Seabed Authority (ISA). Under the plan, any national or private enterprise could take half the seabed mining sites and the ISA would take the other half. In exchange for mining rights, industrialized nations would underwrite the ISA and sell it the necessary technology. In December 1982, 117 nations signed the Law of the Sea Convention at Montego Bay, Jamaica. President Ronald Reagan refused to sign, citing the seabed-mining provisions as a major reason for United States opposition. Two other key nations, the United Kingdom and Germany, refused, and 21 nations abstained. In order to become international law, 60 nations must ratify the Law of the Sea Convention, but although 159 nations have now become signatories, only 40 have actually ratified it. *See also* Coastal Zone Management Act; Commercial fishing; Oil drilling

Convention on the Prevention of Marine Pollution by Dumping of Waste and Other Matter (1972)

The 1972 International Convention on the Prevention of **Marine Pollution** by Dumping of Waste and Other Matter, commonly called the London Dumping Convention, entered into force on August 30, 1975. The London Dumping Convention covers "ocean dumping" defined as any deliberate disposal of wastes or other matter from ships, aircraft, platforms, or other human-made structures at sea. The **discharge** of sewage **effluent** and other material through pipes, wastes from other land-based sources, the operational or incidental disposal of material from vessels, aircraft, and platforms (such as fresh or salt water), or wastes from seabed mining are not covered under this convention.

The framework of the London Dumping Convention consists of three annexes. Annex I contains a blacklist of materials that cannot be dumped at sea. Organohalogen compounds, **mercury**, **cadmium**, oil, high-level radioactive wastes, warfare **chemicals**, and persistent **plastics** and other synthetic materials that may float in such a manner as to interfere with fishing or navigation are examples of substances on the blacklist. The prohibition does not apply to **acid** and alkaline substances that are rapidly rendered harmless by physical, chemical, or biological processes in the sea. Annex I does not apply to wastes such as sewage **sludge** or dredge material that contain blacklist substances in trace amounts.

Annex II of the convention comprises a grey list of materials considered less harmful than the substances on the blacklist. At-sea dumping of grey list wastes requires a special permit from contracting states (countries participating in the convention). These materials include wastes containing

arsenic, **lead**, **copper**, zinc, organosilicon compounds, cyanides, pesticides and radioactive matter not covered in Annex I, and containers, scrap metals, and other bulky debris that may present a serious obstacle to fishing or navigation. Grey list material may be dumped as long as special care is taken with regard to **ocean dumping** sites, monitoring, and methods of dumping to ensure the least detrimental impact on the **environment**. A general permit from the appropriate agencies of the contracting states to the Convention is required for ocean dumping of waste not on either list.

Annex III includes criteria that countries must consider before issuing an ocean dumping permit. These criteria require consideration of the effects dumping activities can have on marine life, amenities, and other uses of the ocean, and they encompass factors related to disposal operations, waste characteristics, attributes of the site, and availability of land-based alternatives.

The International Maritime Organization serves as Secretariat for the London Dumping Convention, undertaking administrative responsibilities and ensuring cooperation among the contracting parties. As of 2001, there were 78 contracting parties to the Convention, including the United States.

The London Dumping Convention covers ocean dumping in all marine waters except internal waters of the contracting states, which are required to regulate ocean dumping consistently with the convention's provisions. However, they are free to impose stricter rules on their own activities than those required by the convention. The London Dumping Convention was developed at the same time as the **Marine Protection, Research and Sanctuaries Act** of 1972 (Public Law 92-532), a law enacted by the United States. The U.S. congress amended this act in 1974 to conform with the London Dumping Convention.

Most nations using the ocean for purposes of dumping waste are developed countries. The United States completely ended its dumping of sewage sludge following the passage of the **Ocean Dumping Ban Act** (1988), which prohibits ocean dumping of all sewage sludge and industrial waste (Public Law 100-688). Britain and the North Sea countries also intend to end ocean dumping of sewage sludge. During the Thirteenth Consultative Meeting of the London Dumping Convention in 1990, the contracting states agreed to terminate all industrial ocean dumping by the end of 1995.

While the volume of sewage sludge and industrial waste dumped at sea is decreasing, ocean dumping of dredged material is increasing. **Incineration** at sea requires a special permit and is regulated according to criteria contained in an addendum to Annex I of the convention.

In 1996, the London Dumping Convention was replaced by the 1996 Protocol to the Convention on the Prevention of Marine **Pollution** by Dumping of Wastes and Other Matter, 1972. Among the changes is the "reverse list." The Protocol only allows dumping material that is listed in Annex I, it is referred to as the "reverse list" since it completely reverses the original Annex I. Incineration at sea is now completely banned, unless there is an emergency, as is the exportation of waste to other countries for ocean dumping. In 2001, the Protocol had been ratified by 16 states, but needs to be ratified by 26, 15 of which must be Contracting Parties to the Convention, in order to be put into force. *See also* Marine pollution; Seabed disposal

Convention on Wetlands of International Importance (1971)

Also called the Ramsar Convention or **Wetlands** Convention, the Convention on Wetlands of International Importance is an international agreement adopted in 1971 at a conference held in Ramsar, Iran. One of the principal concerns of the agreement was the protection of migratory waterfowl, but it is generally committed, like much wetlands legislation in the United States, to restricting the loss of wetlands in general, because of their ecological functions as well as their economic, scientific, and recreational value. The accord went into effect in 1975, establishing a network of wetlands, primarily across Europe and North Africa.

In 2002, there were 132 Contracting Parties, each of whom was required to set aside at least one wetland reserve. Over 1,178 national wetland sites have been established totaling over 252.3 million acres (102.1 million ha). The convention has secured protection for wetlands around the world, but many environmentalists believe it has the same weakness as many international conventions on the **environment**. There is no effective mechanism for enforcement. **Population growth** continues to increase political and economic pressures to develop wetland areas around the world, and there are no provisions in the agreement strong enough

to prevent nations from removing protected status from designated wetlands.

Conventional pollutant

Conventional pollutants fall into five categories; the presence of these pollutants is commonly determined by measuring **biochemical oxygen demand**, total suspended solids, **pH** levels, the amount of fecal coliform, and the quantity of oil and grease.

Biochemical oxygen demand (BOD) is the quantity of oxygen required by **microorganisms** to stabilize five-day incubated oxidizable organic matter at 68°F (20°C). Hence, BOD is a measure of the **biodegradable** organic **carbon** and at times, the oxidizable **nitrogen**. BOD is the sum of the oxygen used in organic matter synthesis and in the endogenous **respiration** of microbial cells. Some industrial wastes are difficult to oxidize, and bacterial seed is necessary. In certain cases, an increase in BOD is observed with an increase in dilution. It is hence necessary to determine the detection limits for BOD.

Suspended solids interfere with the transmission of light. Their presence also affects recreational use and aesthetic enjoyment. Suspended solids make fish vulnerable to diseases, reduce their growth rate, prevent successful development of fish eggs and larvae, and reduce the amount of available food. The **Environmental Protection Agency** (EPA) restricts suspended matter to not more than ten percent of the reasonably established amount for aquatic life. This allows sufficient sunlight to penetrate and sustain **photosynthesis**. Suspended solids also cause damage to invertebrates and fill up gravel spawning beds.

The acidity or alkalinity of water is indicated by pH. A pH of seven is neutral. A pH value lower than seven indicates an acidic **environment** and a pH greater than seven indicates an alkaline environment. Most aquatic life is sensitive to changes in pH. The pH of surface waters is specified to protect aquatic life and prevent or control unwanted chemical reactions such as metal **ion** dissolution in acidic waters. An increase in toxicity of many substances is often observed with changes in pH. For example, an alkaline environment shifts the ammonium ion to a more poisonous form of un-ionized ammonia. EPA criteria for pH are 6.5–9.0 for freshwater life, 6.5–8.5 for marine organisms and 5–9 for domestic consumption.

Fecal **coliform bacteria** are yardsticks for detecting pathogenic or disease causing bacteria. However, this relationship is not absolute because these bacteria can originate from the intestines of humans and other warm blooded animals. Prior knowledge of **river basins** and the possible sources of these bacteria is necessary for a survey to be effective. The strictest EPA criteria for coliforms apply to shellfish, since they are often eaten without being cooked.

Common sources of oil and grease are **petroleum** derivatives and fats from vegetable oil and meat processing. Both surface and domestic waters should be free from floating oil and grease. Limits for oil and grease are based on LC_{50} values. LC_{50} is defined as the concentration at which 50% of an aquatic **species** population perishes. EPA criterion is for a 96-hour exposure, and during this period the concentration of individual petrochemicals should not exceed 0.01 of the LC_{50} median. Oil and grease contaminants vary in physical, chemical, and toxicological properties besides originating from different sources. *See also* Industrial waste treatment; Sewage treatment; Wastewater; Water pollution; Water quality

Copper

A metallic element with an atomic number of 29. It is abbreviated Cu and has an atomic weight of 63.546. Copper is a micronutrient which is needed in many proteins and enzymes. Copper has been and is frequently used in piping systems which convey potable water. Corrosive waters will leach copper from the pipelines, thereby exposing consumers to copper and possibly creating bluish-green stains on household fixtures and clothes. The staining of household fixtures becomes a nuisance when copper levels reach 2–3 mg/l. The drinking water standard for copper is 1 mg/l. It is a secondary standard based on the potential problems of staining and

Copper mining

see **Ashio, Japan; Ducktown, Tennessee; Sudbury, Ontario**

Coprecipitation

Inorganic contaminants, such as **heavy metals**, which exhibit toxicity effects when present at low levels, can be difficult to treat. The level of toxicity can be well below the metal's solubility concentration, and for this reason precipitation, a common treatment method for the removal of heavy metal, does not provide the needed **effluent** quality. **Cadmium**, for instance, has a reported maximum contaminant level (MCL) of 10 μg/l, with a 5 μg/l proposed level. Based upon theoretical solubility calculations, alkaline precipitation may only reduce the level of cadmium to 140 μg/l. Hence, additional methods of **wastewater** treatment are often required to meet environmental regulations. One such treatment technique is chemical coprecipitation.

Coprecipitation is a process in which a solid is precipitated from a solution containing other ions. These ions are incorporated into the solid by **adsorption** on the surface of the growing particles, physical entrapment in the pore spaces, or substitution in the crystal lattice. Adsorption is one of the principle mechanisms of coprecipitation. It is a process in which the solid **species**, or adsorbent, is added to a solution containing other ions, called adsorbates. In this case, the adsorbates are bound to the solid's surface by physical or chemical interactions between one adsorbate and the adsorbent.

In solution, coprecipitation and adsorption are thus related by the time during which an adsorbate is present. The type of adsorbent present also affects the extent of **ion** uptake from solution. One solid used to perform this treatment is ferric oxide. For example, iron coprecipitation of cadmium has been reported to yield a residual cadmium concentration of about 3 μg/l. Several solid and solution variables must be considered when designing and optimizing coprecipitation as a treatment option. These include the equilibrium concentration of the species in solution, the suspension **pH**, and the presence of other interacting ions. Also, the properties of the solid adsorbent are important. These include type of solid formed, surface area available, age, and surface charge. In short, coprecipitation is controlled by a number of important variables which are specific to a given system. Thus treatability studies must be performed to fully optimize this wastewater treatment process and produced the necessary effluent quality. *See also* Hazardous waste; Pollution control; Sewage treatment; Toxic substance

Coral bleaching

Coral bleaching is the whitening of coral colonies due to the loss of the symbiotic algae, zooxanthellae, from the tissues of coral polyps. It is mostly caused by stress. The host coral polyp provides the algae with a protected **environment** and a supply of **carbon dioxide** for its photosynthetic processes. The golden-brown algae serve as a major source of nutrition and color for the coral. The loss of the algae exposes the translucent calcium carbonate skeletons of the coral colony, and the corals look "bleached." Corals may recover from short-term bleaching (less than a month), but prolonged bleaching causes irreversible damage and **mortality**, for without the algae, the corals starve and die. However, even a sublethal stress may result in increased susceptibility of corals to infections, with resulting significant mortality. Populations of sea urchins, parrot fish, and worms erode and weaken dead reef skeletons, and the reef can be destroyed by storm surges.

The means by which corals expel the zooxanthellae are not yet known. In laboratory experiments the zooxanthellae are released into the gut of the polyp and then expelled through the mouth; however this method has not been observed in the environment. Another hypothesis is that the stressed corals provide the algae with fewer nutrients, which results in the algae leaving the corals. Another possibility is that the algae may produce oxides under stress, which adversely affect the algae.

Bleaching may be caused by a number of stresses or environmental changes, including disease, excess shade, increased levels of **ultraviolet radiation**, **sedimentation**, **pollution**, **salinity** changes, exposure to air by low tides or low sea level, and increased temperatures. Coral bleaching is most often associated with increased sea surface temperatures, as corals tolerate only a narrow temperature range of between about 77–84°F (25–29°C).

Historically bleaching was observed on a small scale, such as in overheated tide pools. However, in the early to mid 1980s, coral reefs around the world began to experience large scale bleaching, with a bleaching event occurring somewhere in the world almost every year. In 1998, coral reefs around the world suffered the most extensive and severe bleaching and subsequent mortality in recorded history, in the same year that tropical sea surface temperatures were the highest in recorded history. Coral bleaching was reported in at least 60 countries and island nations in the Pacific Ocean, Indian Ocean, Red Sea, Persian Gulf, and the Caribbean. Only the Central Pacific region was spared. About 16% of the world's reefs were lost in a period of only nine months. Previous bleaching events had only affected reefs to a depth of less than 49 ft (15 m), but in 1998, the bleaching extended as deep as 164 ft (50 m). The reason sea temperatures throughout the world were so warm in 1998 remains controversial and uncertain. Three theories have been developed—natural **climate** variability, El Ninño and other climatic variations, and global warming. By the end of 2000, 27% of the world's reefs had been lost, with the largest single cause being the coral bleaching event of 1998. Only half of the reefs lost during 1998 will probably recover, which will add to the 11% already lost to human impacts such as **sediment** and **nutrient** pollution and overexploitation.

Many of the bleached **coral reef** ecosystems may require decades to recover. Human populations dependent on the reefs will lose fisheries, shoreline protection, and tourism opportunities. Trends of the past century indicate that coral bleaching events may become more frequent and severe if the climate continues to warm.

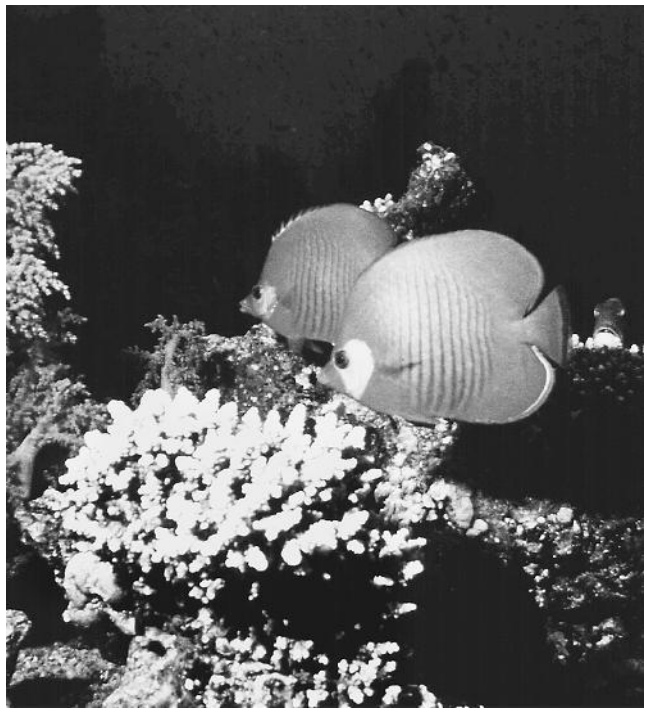
Coral reef

Coral reefs represent some of the oldest and most complex communities of plants and animals on Earth. About 200–400 million years old, they cover about 231,660 mi^2 (600,000 km^2) worldwide. (The most popular reefs range from 5,000–10,000 years old.) The primary structure of a coral reef is a calcareous skeleton formed by marine invertebrate organisms known as *cnidarians*, which are relatives of sea anemones. Corals are found in most of the oceans of the world, in deep as well as shallow seas and temperate as well as tropical waters. But corals are most abundant and diverse in relatively shallow tropical waters, where they have adapted to the constant temperatures provided by these waters. The reef-forming corals, or hermatypic corals, have their highest diversity in the Indian and Pacific Oceans, where over 700 **species** are found. By contrast, the Atlantic Ocean provides the **habitat** for less than 40 species. Other physical constraints needed for the success of these invertebrate communities are clear water, a firm substrate, high **salinity**, and sunlight. Clear water and sunlight are required for the symbiotic unicellular plants that live in the surface tissues of the coral polyps. This intimate plant-animal association benefits both participants. Corals obtain oxygen directly from the plants and avoid having to excrete nitrogenous and phosphate waste products because these are absorbed directly as nutrients by the plants. **Respiration** by the coral additionally provides **carbon dioxide** to these plants to be used in the photosynthetic process.

The skeletons of hermatypic coral play a major role in the formation of coral reefs, but contributions to reef structure, in the form of calcium carbonate, come from a variety of other oceanic species. Among these are red algae, green algae, foraminifers, mollusk shells, sea urchins, and the exoskeletons of many other reef-dwelling invertebrates. This limestone infrastructure provides the **stability** needed, not only to support and protect the delicate tissues of the coral polyps themselves, but also to withstand the constant wave action generated in the shallow, near-shore waters of the marine **ecosystem**.



There are essentially three types of coral reefs. These categories are fringing reefs, barrier reefs, and atolls. Fringing reefs form borders along the shoreline. Some of the reefs found in the **Hawaiian Islands** are fringing reefs. Barrier reefs also parallel the shoreline but are found further offshore and are separated from the coast by a **lagoon**. The best example of this type of reef is the **Great Barrier Reef** off the coast of **Australia**. Because the coral colonies form an interwoven network of organisms from one end of the reef to the other, this is the largest individual biological feature on earth. The Great Barrier Reef borders about 1,250 mi (2011 km) of Australia's northeast coast. The second largest continuous barrier reef is located in the Caribbean Sea off the coast of Belize, east of the Yucatan Peninsula. The third type of reef, the atoll, is typically a ring-shaped reef, from which several small, low islands may project above the surface of the ocean. The ring structure is present because it represents the remains of a fringing reef that formed around an

oceanic **volcano**. As the volcano eroded or collapsed, the outwardly-growing reef is ultimately all that remains as a circle of coral. Possibly the most infamous atoll is the **Bikini Atoll**, which was the site of the United States' **hydrogen** bomb tests during the 1940s and 1950s.

Besides the physical structure of the coral and the reef itself, the most significant thing about these structures is the tremendous diversity of marine life that exists in, on, and around coral reefs. These highly productive marine ecosystems may contain over 3,000 species of fish, shellfish, and other invertebrates. About 33% of all of the fishes of the world live and depend on coral reefs. This tremendous diversity provides for a huge commercial fishery in countries such as the Philippines and Indonesia. With the advent and availability of SCUBA gear to the general public in this half of this century, the diversity of life exhibited on coral reefs has been a great lure for tourists to these ecosystems throughout the world.

Even with their calcium carbonate skeleton and exquisite beauty, coral reefs are being degraded and destroyed daily, not only by natural events such as constant wave action and storm surges, but, more importantly, by the actions of man. Of the 109 countries that have coral reef formations within their territorial waters, 90 are losing them because of man-induced **environmental degradation**. Most is the result of physical abuse or **pollution** which alters the narrow range of physical and chemical parameters necessary for the coral, or their plant symbionts, to remain viable and thrive. Today, 10% of the world's coral reefs are completely degraded, 30% have reached a critical stage. Scientists have determined that if degradation at this rate continues, 70% of all coral reefs could be gone in 40 years. Reefs can be salvaged however. In 1995, participants from 44 countries representing governments, nongovernmental organizations, international development agencies, and the private sector gathered to launch the International Coral Reef Initiative. In 1997, some 1,400 participants declared the year as the International Year of the Reef, a period they hoped would heighten awareness and further reef salvage activities worldwide.

These reefs, most of which are between 5,000 and 10,000 years old, and some of which have been building on the same site for over a million years, are being degraded and destroyed by a vast array of water pollutants. **Silt**, which washes into the sea from **erosion** of clearcut forests miles inland, cloud the water or smother the coral, thus prohibiting the photosynthetic process from taking place. **Oil spills** and other toxic or hazardous **chemicals** that find their way into the marine ecosystem through man's actions are killing off the coral and/or the organisms associated with the reefs. Mining of coral for building materials takes a massive toll on these communities. Removal of coral to supply the ever increasing demand within the **aquarium trade** is destroying the reefs as well. The tremendous interest in and appeal of marine aquaria has added another problem to this dilemma. In the race to provide the aquarium market with a great variety of beautiful, brilliantly-colored, and often quite rare, marine fishes, unscrupulous collectors, who are selling their catches illegally merely for the short term monetary gain, spray the coral heads with poison solutions (including cyanide) to stun the fishes, causing them to abandon the reefs. This efficient means of collecting reef fishes leaves the coral head enveloped in a cloud of poison, which ultimately kills that entire section of the reef.

A coral reef. (Phototake. Reproduced by permission.)

An unusual phenomenon has developed within the past decade with regard to coral reefs and pollution. In the Florida Keys in the early 1980s divers began reporting that the coral, sea whips, sea fans, and sponges of the reefs, around which they had been swimming, had turned white. They also reported that the waters felt unusually warm. The same phenomenon occurred in the Virgin Islands in the late 1980s. As much as 50% of the reef was dying due to this bleaching effect. Scientists are still studying these occurrences; however, many feel that it is a manifestation of global warming, and that a mere change in the water temperature around the coral reefs of 2–3°C is inducing the bleaching and death of the coral.

Tourism and **recreation** are inadvertently degrading coral reefs throughout the world as well. Coral is being destroyed by the propellers of recreational boats as well as divers who unintentionally step on coral heads, thus breaking them to pieces, and degrading the very structure of the ecosystem they came to see. Many of the reefs undergoing this degradation are sections that have been set aside for protection. Even with almost a quarter of a million square miles of coral reefs in the world, and about 300 protected regions in 65 countries, ever increasing levels of near-shore pollution, coupled with other acts of man, may be destroying these extremely complex communities of marine organisms at a rate faster than we can control.

Corporate Average Fuel Economy standards

In 1975, as part of the response to the Arab **oil embargo** of 1973–1974, the U.S. Congress and President Richard Nixon passed the **Energy Policy** and **Conservation** Act. One of a number of provisions in this legislation intended to decrease fuel consumption was the establishment of fuel economy standards for passenger cars and light trucks sold in the United States. These Corporate Average Fuel Economy (CAFE) standards require that each manufacturer's entire production of cars or trucks sold in the United States meet a minimum average fuel economy level. Domestic and import cars and trucks are segregated into separate fleets, and each must meet the standards individually. Any manufacturer whose fleet(s) fails to meet the standard is subject to a fine, based on a CAFE shortfall times the total number of vehicles in the particular fleet. Manufacturers are allowed to generate CAFE credits for overachievement in a single year, which may be carried forward or backward up to three years to cover other shortfalls in mileage. This helps to smooth the effects of model introduction cycles or market shifts.

CAFE standards took effect in 1978 for passenger cars and 1979 for light trucks. Truck standards originally covered vehicles under 6,000 lb (2,724 kg) gross vehicle weight (GVW), but in 1980, they were expanded to trucks up to 8,500 lb (3,632 kg). Car standards were set at 18 mpg for 1978, and increased annually to 27.5 mpg for 1985 and beyond. Manufacturers responded with significant vehicle downsizing, application of new powertrain technology, and reductions in aerodynamic drag and tire friction. These actions helped improve average fuel economy of U.S.-built passenger cars from 13 mpg in 1974 to 25 mpg by 1982. The fall of **gasoline** prices following an embargo in 1980–1981 encouraged consumers to purchase larger vehicles. This mix shift slowed manufacturers' CAFE improvement by the mid-1980s, despite continued improvements in individual model fuel economy, since CAFE is based on all vehicles sold. The Secretary of **Transportation** has the authority to reduce the car CAFE standards from 27.5 mpg to 26 mpg. This authority was used in 1986 when it became clear that market factors would prevent CAFE compliance by a large number of manufacturers.

A separate requirement to encourage new car fuel efficiency was created through the Energy Tax Act of 1978. This act created a "Gas Guzzler" tax on passenger cars whose individual fuel economy value fell below a certain threshold, starting in 1980. The tax is progressively higher at lower fuel economy levels. This act has since been amended both to increase the threshold level and to double the tax. The Gas Guzzler tax is independent of CAFE standards.

Environmental groups have long favored increasing the CAFE standards to reduce oil consumption and **pollution**. At the same time, the **automobile** industry has fought hard to avoid raising mileage standards, claiming increased regulation would reduce competitiveness and cost jobs. After the **Persian Gulf War** in 1991, some members of Congress proposed raising CAFE standards to 45 mpg for cars and 35 mpg for light trucks by 2001. Proponents of the plan claimed it would save 2.8 million barrels of oil per day, or more oil than is imported from Persian Gulf countries (about 2.4 million barrels per day in 2000). Strongly opposed by the automobile industry, the efficiency increase failed in Congress.

Cheap oil prices in the 1990s decreased Americans' concerns about fuel efficiency, and sales of larger cars boomed. Since 1988, nearly all technology gains in automobile efficiency have been offset by increased weight and power in new vehicles. The popular Sport Utility Vehicle (SUV), decried by environmentalists, became the new model of gas guzzler. Due to the "SUV loophole" in the CAFE laws, the SUV was classified as a light truck and was exempted from higher mileage standards and fines for inefficiency, although opponents of the vehicles claim that they are used more like cars and should be classified as such. By law, SUVs can emit up to five times more **nitrogen oxides** than cars, and have a lower fleet mileage standard of 20.7 mpg. By 2001, SUVs and light trucks accounted for nearly half of all new automobiles sold. Because of the high sales

of large vehicles, United States automobile efficiency reached its lowest point in 21 years in 2001, despite new technology.

Another battle between environmentalists and the automobile industry occurred in March 2002, when Congress considered raising CAFE standards by 50% by the year 2015. Environmental and other groups claimed that increased efficiency would reduce America's dependence on foreign oil, would reduce pollution and **greenhouse gases** in the **environment**, and eliminate the need to drill for oil in sensitive regions such as the **Arctic National Wildlife Refuge** (ANWR) and offshore areas. The bill was strongly opposed by the automobile industry, and did not pass.

Corrosion and material degradation

Corrosion or degradation involves deterioration of material when exposed to an **environment** resulting in the loss of that material, the most common case being the corrosion of metals and steel by water. The changes brought about by corrosion include weight loss or gain, material loss, or changes in physical and mechanical properties.

Metal corrosion involves oxidation-reduction reactions in which the metal is lost by dissolution at the anode (oxidation). The electrons travel to the cathode where the reduction takes place, while s move through a conducting solution or electrolyte. A positive and a negative pole, called the cathode and the anode respectively, are thereby created with a current flow between them. Thus the process of corrosion is basically electrochemical.

For corrosion to occur, certain conditions must be present. These are: (1) a potential difference between the cathode and the anode to drive the reaction; (2) an anodic reaction; (3) an equivalent cathodic reaction; (4) an electrolyte for the internal circuit; (5) an external circuit where electrons can travel. Sometimes, polarization of the anodic and the cathodic reactions must be taken into consideration. Polarization is a change in equilibrium **electromagnetic field** of a cell due to current flow. It has been reported that polarization may retard corrosion, as in the accumulation of unreacted **hydrogen** on the cathode.

In the corrosion of iron in water, the reactions differ according to whether or not oxygen is present. The common reactions that take place in a deaerated medium are essentially an oxidation reaction releasing ferrous **ion** into solution at the anode and a reduction reaction releasing hydrogen gas at the cathode. In the presence of oxygen, a complementary cathode reaction involves oxygen being reduced to water.

Degradation of concrete, on the other hand, depends on the composition of cement and the aggressive action of the water in contact with it. Some forms of corrosion may be visibly apparent, but some are not. Surface corrosion, corrosion at discrete areas, and anodic attack in a two-metal corrosion may be readily observed. A less identifiable form, erosion-corrosion, is caused by flow patterns that cause abrasion and wear or sweep away protective films and accelerate corrosion. Another form of corrosion which involves the selective removal of an alloy constituent requires another means of examination. Cracking, a form of corrosion which is caused by the simultaneous effects of tensile stress and a specific corrosive medium, could be verified by microscopy.

Some measures adopted to prevent corrosion in metals are cathodic protection, use of inhibitors, coating, and the formation of a passivating film. Protection of concrete, on the other hand, can be achieved by coating, avoiding corrosive **pH** of the water with which the concrete is in contact, avoiding excessive concentrations of ammonia, and avoiding deaeration in pipes. *See also* Hazardous waste sites; Seabed disposal; Waste management

Cost-benefit analysis

Environmentalists might believe that total elimination of risk that comes with **pollution** and other forms of **environmental degradation** is possible and even desirable, but economists argue that the benefits of risk elimination have to be balanced against the costs. Measuring risk is itself very complicated. **Risk analysis** in the case of pollution, for instance, involves determining the conditions of exposure, the adverse effects, the levels of exposure, the level of the effects, and the overall contamination. Long **latency** periods, the need to draw implications from laboratory studies

A cost-benefit analysis. (McGraw-Hill Inc. Reproduced by permission.)

of animal **species**, and the impact of background contamination complicate these efforts. Under these conditions, simple cause and effect statements are out of the question.

The most that can be said in health **risk assessment** is that exposure to a particular pollutant *is likely* to cause a particular disease. Risk has to be stated in terms of probabilities, not certainties, and has to be distinguished from safety, which is a societal judgment about how much risk society is willing to bear. When assessing the feasibility of technological systems, different types of risks—from mining, radiation, industrial accidents, or **climate** impacts, for example—have to be compared. This type of comparison further complicates the judgments that have to be made.

Reducing risk involves asking to what extent the proposed methods of reduction are likely to be effective, and how much these proposed methods will cost. In theory, decision making could be left to the individual. Society could provide people with information and each person could then decide whether to purchase a product or service, depending upon the environmental and resource consequences. However, relying upon individual judgments in the market may not adequately reflect society's preference for an amenity such as **air quality**, if that amenity is a public good with no owner and no price attached to it. Thus, social and political judgments are needed.

However much science reduces uncertainty, gaps in knowledge remain. Scientific limitations open the door for political and bureaucratic biases that may not be rational. In some instances, politicians have framed legislation in ways that seriously hinder if not entirely prohibit the consideration of costs (as in the **Delaney Clause** and the **Clean Air Act**). In other instances, of which the President's **Regulatory Review** Council is a good example, they have explicitly required a consideration of cost factors.

There are different ways that cost factors can be considered. Analysts can carry out cost effectiveness analyses, in which they attempt to figure out how to achieve a given goal with limited resources, or they can carry out more formal risk-benefit and cost-benefit analyses in which they have to quantify both the benefits of risk reduction and the costs.

Economists admit that formal, quantitative approaches to balancing costs and benefits do not eliminate the need for qualitative judgments. Cost-benefit analysis

initially was developed for water projects where the issues, while complicated, were not of the same kind as society now faces. For example, how does one assess the value of a magnificent vista obscured by **air pollution**? What is the loss to society if a given genetic strain of grass or animal species becomes extinct? How does one assess the lost opportunity costs of spending vast amounts of money on air pollution that could have been spent on productivity enhancement and global competitiveness?

The most recalcitrant question concerns the value of human life. Cost-benefit analysis requires quantifying the value of a human life in dollars, so that specific health risks can be entered into the calculations against the cost of reducing such risks. Many different methods of arriving at an appropriate figure have been undertaken, all with predictably absurd results. Estimates range from $70,000 to several million dollars a head. Although the question does not admit of a sensible answer, society must nevertheless decide how much it is willing to pay to save a given number of lives (or how much specific polluters should pay for endangering them).

Equity issues (both interpersonal and intergenerational) cannot be ignored when carrying out cost-benefit analysis. The costs of air pollution reduction may have to be borne disproportionately by the poor in the form of higher **gasoline** and **automobile** prices. The costs of **water pollution** reduction, on the other hand, may be borne to a greater extent by the rich because these costs are financed through public spending. Regions dependent on dirty **coal** may find it in their interests to unite with environmentalists in seeking **pollution control** technology. The pollution control technology saves coal mining jobs in West Virginia and the Midwest, where the coal is dirty, but draws away resources from the coal mining industry in the West where large quantities of clean-burning coal are located.

Intergenerational equity also plays a role. **Future generations** have no current representatives in the market system or political process. How their interests are to be taken into account ultimately amounts to a philosophical discussion about altruism: to what extent should current generations hold back on their own consumption for the sake of posterity? Should Jeremy Bentham's utilitarian ideal of "achieving the greatest good for the greatest number" be modified to read "achieving sufficient per capita product for the greatest number over time?" *See also* Environmental economics; Intergenerational justice; Pollution control costs and benefits; Risk analysis

Douglas M. Costle (1939 –)

American former director of Environmental Protection Agency

An educator and an administrator, Douglas M. Costle helped design the **Environmental Protection Agency** (EPA) under Richard Nixon and was appointed to the head of that agency by Jimmy Carter. Costle was born in Long Beach California on July 27, 1939, and spent most of his teenage years in Seattle. He received his B.A. from Harvard in 1961 and his law degree from the University of Chicago in 1964. His career as a trial attorney in the civil rights division of the Justice Department began in Washington in 1965. Later he became a staff attorney for the Economic Development Administration at the Department of Commerce.

In 1969, Costle was appointed to the position of senior staff associate of the President's Advisory Council on Executive Organization, and in this post was instrumental in the formation of the EPA. Although Costle lobbied to be appointed as assistant administrator of the new agency, his strong affiliations with the Democratic party seem to have hindered his bid. Instead he continued as a consultant to the agency for two years and an adviser to the President's **Council on Environmental Quality**.

The road that led Costle back to the EPA took him to Connecticut in 1972, where he became first deputy commissioner and then commissioner of the Department of Environmental Protection in that state. He proved himself an able and efficient administrator there, admired by many for his ability to work with industry on behalf of the **environment**. His most important accomplishment was the development of a structure often called the "Connecticut Plan," where fines for industrial **pollution** were calculated on the basis of the costs that business would have incurred if it had complied with environmental regulations.

Carter appointed Costle head of EPA in 1977 as a compromise candidate during a period of bitter feuding over the direction of the agency (then at the center of a debate over the economic effects of regulation). But many environmentalists believed Costle's record proved he compromised too willingly with business, and they openly questioned whether he had the political strength to support environment protection in the face of fierce political and industrial opposition.

By May of his first year in office he was able to secure funding for 600 additional staff positions in the EPA, and under him much was done to provide a rationale

for the regulations he had inherited and base them wherever possible on scientific data. Among other decisions Costle made while head of the EPA, he recommended a delay on the imposition of new auto emissions standards, allowed the construction of the nuclear plant in Seabrook, New Hampshire to continue despite protests, and oversaw the formation of an agreement with U.S. Steel on the reduction of air and **water pollution**.

Throughout his tenure Costle remained a strong proponent of the view that the federal government's responsibility to the environment was not incompatible with the obligations it had to the economy. He often argued that environmental regulation actually assisted economic development. Although conflicts with lobbying groups and hostile litigation, as well as increased controversy over the inflationary effects of environmental regulation, complicated his stewardship of the EPA, Costle continued to believe in what he called a gradual and "quiet victory" for environmental protection.

Costle went on to become chairman of the U.S. Federal Regulatory Council until 1981. He is now a retired dean of Vermont Law School in South Royalton.

Council on Environmental Quality

Until it was abolished by the Clinton Administration in 1993, the President's Council on Environmental Quality (CEQ) was the White House Office that advised the President and coordinated executive branch policy on the **environment**. CEQ was established by the **National Environmental Policy Act** (NEPA) of 1969 to "formulate and recommend national policies" to promote the improvement of the quality of the natural environment.

CEQ had three basic responsibilities: to serve as advisor to the President on **environmental policy** matters; to coordinate the positions of the various departments and agencies of government on environmental issues; and to carry out the provisions of NEPA. The latter responsibility included working with federal agencies on complying with the law and issuing the required regulations for assessing the environmental impacts of federal actions. (NEPA requires that all agencies of the federal government issue "a detailed statement" on "the environmental impact" of "proposals for legislation and other major federal actions significantly affecting the quality of the human environment." This seemingly innocuous provision has been used often by environmental groups to legally challenge federal projects that might damage the environment, on the grounds that the required **Environmental Impact Statement** was inadequate or had not been issued.)

CEQ also prepared and issued the annual Environmental Quality Report; administered the President's Commission on Environmental Quality, an advisory panel involved in voluntary initiatives to protect the environment; and supervised the President's Environment and **Conservation** Challenge Awards, which honored individuals and organizations who achieved significant environmental accomplishments. Under the Nixon and Carter administrations, CEQ had a significant impact on the formulation and implementation of environmental policy. But its role was greatly diminished under the Reagan and Bush administrations, which paid much less attention to environmental considerations.

Perhaps CEQ's best-known and most influential accomplishment was its landmark work, *The Global 2000 Report to the President*, prepared with the U.S. Department of State and other federal agencies, and released in July 1980. This pioneering study was the first report by the U.S. government—or any other—projecting long term environmental, population, and resource trends in an integrated way.

Specifically, the report projected that the world of the future would not be a pleasant place to live for much of humanity, predicting that "if present trends continue, the world in 2000 will be more crowded, more polluted, less stable ecologically and more vulnerable to disruption than the world we live in now. Serious stresses involving population, resources, and environment are clearly visible ahead....the world's people will be poorer in many ways than they are today." CEQ's *Eleventh Annual Report, Environmental Quality—1980*, further warned that "we can no longer assume, as we could in the past, that the earth will heal and renew itself indefinitely. Human numbers and human works are catching up with the earth's ability to recover...The quality of human existence in the future will rest on careful stewardship and husbandry of the earth's resources."

In the following dozen years, CEQ was much more reluctant to speak out about the ecological crisis. Early in his presidency, Bill Clinton abolished CEQ and created the White House Office on Environmental Policy to coordinate the environmental policy and actions of his administration. Clinton said this new body will "have broader influence and a more effective and focused mandate to coordinate policy" than CEQ had.

Jacques-Yves Cousteau (1910 – 1997)

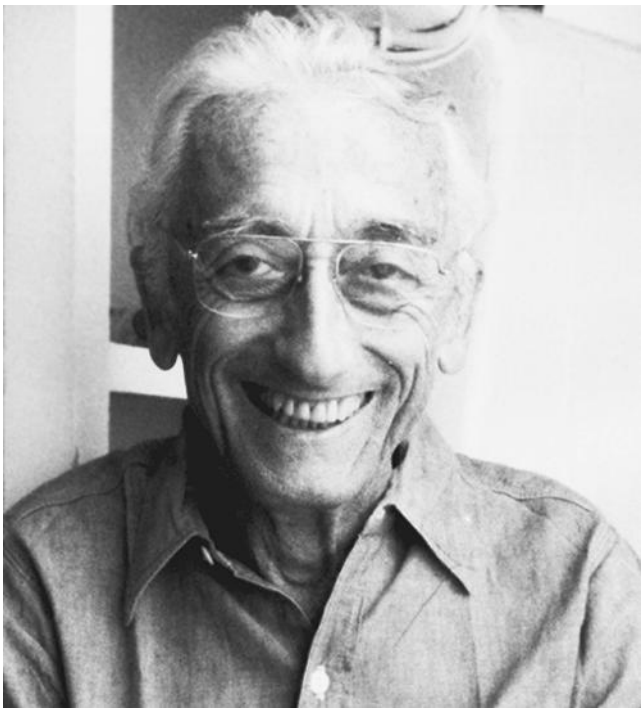
French oceanographer, inventor, photographer, explorer, and environmentalist

When most people think of marine biology, the person that immediately comes to mind is Jacques-Yves Cousteau. Whether through invention, research, **conservation**, or education, Cousteau has brought the ocean world closer to scientists and the public, and it is the interest, awareness, and appreciation fostered through Cousteau's work that may ultimately save the marine **environment** from impending destruction.

Born in France in 1910, Cousteau's childhood was full of illnesses that left him anemic. His sickness, however, did not stop him from being an independent thinker, a trait that led to his strong commitment to oceanographic research. He attended the École Navale in Brest, France, the national naval academy, where his interest in marine research was sparked by a cruise around the world on the school ship *Jeanne D'Arc*. Cousteau brought his camera and filmed a rough documentary of the voyage. His fascination with pearl and fish divers, and his ability to use a camera, would revolutionize undersea exploration.

During World War II, Cousteau, his wife, and two friends made masks and snorkels from inner tubes and garden hose. Through experimentation, they discovered that the worst enemy of a diver was the cold, and Cousteau proceeded to work on an effective diving suit. In 1943, Cousteau and Emile Paul Gagnon patented the Aqua Lung, the first self-contained underwater breathing apparatus (SCUBA). It was this invention that led to Cousteau being known as the "father of modern diving." SCUBA has opened a new world to scientific research as it is used extensively not only in marine biology, but also in marine geology, archaeology, and chemical oceanography.

Cousteau's innovations did not end with the Aqua Lung. He combined his interests in diving and photography to develop the first underwater camera housing. While stationed with the Navy in Marseilles, Cousteau continued to develop underwater photographic equipment, including battery packs and lights. In 1943, Cousteau and several friends filmed "Wrecks," a documentary of a sunken ship in the **Mediterranean Sea**. The French navy recognized Cousteau's talent and thought that this technology could be useful in recovering German mines and retrieving lost cargo. He was promoted to commandant and was put in charge of the Undersea Research Group, where he continued to develop diving and photographic techniques.



In 1950, Cousteau realized that the vessel donated to the Undersea Research Group was inadequate and asked the navy to furnish them with another ship. When the French navy refused, Cousteau formed a non-profit organization, Campagnes Oceanographique Françaises, and was able to raise enough money to purchase and refit an old British minesweeper. This would become the most famous and recognized scientific research vessel in the world: *Calypso*.

Cousteau first gained notoriety in the United States in the early 1950s when *Life Magazine* and *National Geographic* introduced Americans to the undersea endeavors of Cousteau and his Undersea Research Group. In 1953 Cousteau was persuaded to translate his journals into English and published them as *The Silent World*. It sold five million copies and was translated into twenty-two languages. It was filmed as a documentary in 1955 and won an Academy Award and the Gold Medal at the Cannes Film Festival that year. Following the commercial success of his film, Cousteau was appointed director of the world's oldest and largest marine research center, the Oceanographic Institute of Monaco. He rebuilt the deteriorating institute, adding aquariums and many live specimens collected during his travels.

While trying unsuccessfully to house **dolphins** in the facility, Cousteau developed a respect for the intelligence of these animals. This prompted him to campaign for stopping the slaughter of dolphins for use in pet foods. This was to be the first of many environmental campaigns for Cousteau, during which he discovered that the public, once educated about the environment, would be willing to try to preserve it. This theme of education has guided **the Cousteau Society**, and many other environmental organizations, ever since.

Exploring depths deeper than possible with SCUBA intrigued Cousteau and, in 1960, he tested the DS-2 diving saucer, in which he dove to over 984 ft (300 m) in the Bay of Ajaccio, near Corsica. After hundreds of successful dives, Cousteau started Continental Shelf Station Number One (Conshelf I) in the Mediterranean. This experiment not only investigated deep undersea habitats, but also determined how divers would respond to life underwater for long periods of time while conducting laboratory experiments. The work

Jacques Cousteau. (Corbis-Bettmann. Reproduced by permission.)

performed by Cousteau and his research group not only laid the groundwork for all subsequent submersible engineering and exploration, but also was one of the first thorough investigations of hyperbaric physiology.

In 1966, Cousteau began that for which he is best known: television documentaries. With the airing of "The World of Jacques Cousteau," millions were introduced to the wonders of the sea. That same year, Cousteau signed a contract and began to film "The Undersea World of Jacques Cousteau," which ran for nearly nine years, giving Americans a glimpse of marine environments and the behaviors of the organisms that live there. The series, now in syndication, continues to fascinate generations of Americans and spawn interest in marine science and conservation.

In the early 1970s, Cousteau became frustrated with increasing **marine pollution** and produced a series of documentaries focusing on the destruction of marine systems. He also expanded his explorations to riverine systems, lakes, **rain forest** destruction and the conflicts between human culture and the environment. The scope of his films demonstrates Cousteau's devotion to preserving all natural systems.

Cousteau's accomplishments are numerous. He had published more than 18 books and contributed many articles to professional and popular journals. His documentary films have won three Academy Awards and his series, "The Undersea World of Jacques Cousteau," has won numerous Emmy Awards. Many organizations have recognized Cousteau for his work in technical fields as well as in conservation. These awards include Gold Medals from the National Geographic Society and the Royal Geographical Society, and the United Nations international environmental award. He has received honorary degrees from the University of California at Berkeley, Brandeis University, Rensselaer Polytechnic Institute, Harvard University, the University of Ghent, and the University of Guadalajara. He was named to the U.S. **National Academy of Sciences** in 1968.

Cousteau's devotion to the natural world has not been with out its costs. His son Philippe was killed in a diving accident and numerous financial difficulties, especially early in his career, set back his work. Whether it is in oceanographic research, marine engineering, the development and manufacture of diving equipment, the production of films and television specials, or **environmental education**, Cousteau continued to inspire and fascinate, motivating scientists and the public alike to work to preserve the ocean world until his death Paris on July 25, 1997.

Cousteau Society, The

The Cousteau Society is a non-profit organization dedicated to marine research, especially underwater exploration and filmmaking. Created in 1973 by **Jacques-Yves Cousteau** and his son, Jean-Michel Cousteau, the Society provides educational materials, and sponsors or cosponsors scientific, technological and environmental research studies to gauge the health of the world's marine environments.

The Society's educational projects include award-winning television specials that inspire interest in the marine world. Special reports filmed and broadcast have included those on the ***Exxon Valdez*** oil spills and the natural history of the great white shark (Carcharodon charcharias). Cousteau films are broadcast in more than 100 countries and to schools around the world. Books and filmstrips on marine and environmental issues are produced for colleges, schools, and the public. The Society produces two periodicals that explain scientific and environmental issues, the *Calypso Log* for adults and the *Dolphin Log* for youngsters.

The Society's Project Ocean Search offers field study programs under the supervision of Society educators and scientists. Presently, the Society is developing Cousteau Center sites that will provide visitors with ocean experiences through the use of film and illusion technology. The Society also sponsors research to help the scientific community better understand the nature of a region or phenomenon, as well as studies designed to provide local policy makers with guidelines to protect their **environment**.

Two Cousteau Society research vessels, *Calypso* and *Alcyone*, are circumnavigating the globe to take a fresh look at the planet. Four hours of television documentaries are filmed each year about those expeditions. Scientific teams aboard the two research vessels are measuring the productivity of the oceans, studying the contributions of rivers to ocean vitality, assessing the health of marine and freshwater habitats, and exploring the global connections between major components of the **biosphere** such as tropical forests, rivers, the **atmosphere**, seas, oceans, and humankind.

The Society also provides assistance to the Marine Mammal Stranding Program, a network of scientists and others who study strandings of **whales** and **dolphins**. With the Smithsonian Institution, the Society sponsors the Marine Mammal Events Program, which gathers information on beach stranding reports from the United States and other parts of the world to create a centralized data base. The compilation is expected to lead to a better understanding of the phenomenon of beaching.

Currently, the Society is developing educational computer programs for young people that explore the consequences of various actions on the environment; and it is preparing environmental cartoon books for students in developing countries. It also supports the development of new technologies that will help provide solutions to environmental challenges.

Coyote

The name coyote comes from the Aztec name *Coyoti*. The Latin name for the coyote is *Canis latrans* which means barking dog. A member of the family Canidae, the coyote is also called God's Dog, brush wolf, **prairie** wolf, and the Songdog.

Coyotes are especially important to biologists and others studying **wildlife** and the **environment** both because of their ability to control their own population and because of their effect upon other wildlife populations, especially that of the white-tailed deer.

The coyote is roughly the size of a small German Shepherd, weighing from 20–35 lb (9–14 kg) and 4–5 ft (1.2–1.5 m) long, although some can grow as large as 50 lb (23 kg) in the northern and northeastern part of their range. The coat of a coyote can be gray or brownish gray, depending on the season and **habitat**, with a bushy tail that is tipped with black. Coyote fur is long and soft and grows heavier in the winter to protect it from the cold. Its fur also grows lighter in color in the winter and darker in the summer to help it blend in with its natural surroundings.

The early European settlers originally found the coyote only in Central and western North America. However, despite many attempts by humans to get rid of them, coyotes today range from Panama to Northern Alaska, and from California to Newfoundland. They have been seen in every state in the continental United States, but since they are predominately nocturnal, are too elusive to count accurately. Coyotes have even been found in isolated regions such as Cape Cod, as well as in various urban areas such as Chicago, Los Angeles, and New York City.

This ongoing expansion of the coyote's range began in the late 1800s, soon after the United States government began programs of killing them in order to protect domestic livestock, especially the sheep that were **grazing on public lands**. However, unlike the **overhunting** of other **species**, such as the passenger pigeons, grizzly bears, **wolves**, and **whales**, the best efforts to kill off the coyotes have all failed, and coyotes have continued to thrive. Biologists now believe that the coyote population has more than doubled since 1850.

Several factors account for this expansion. Farming and the clearing of the unbroken forests that once covered much of North America have created new and more suitable habitats. The eradication of the wolf in much of North America has removed one of the coyote's major predators and has led to less **competition** for many prey animals. Unlike the wolf, the coyote has more easily adapted to changing habitats, and has adjusted to living close to human populations. In addition, the introduction of sheep and other domestic animals has given the coyote new food sources.

Coyotes are opportunistic carnivores with a variable diet depending on the season or habitat. Although they prefer rodents, rabbits, and hares, they are definitely not picky. They will emulate the larger wolf and hunt deer, elk, and sheep in packs. They will also eat carrion and have been

known to eat grasshoppers, beetles, snakes, lizards, **frogs**, rats, domestic cats, porcupines, turtles, and even watermelons and wild blueberries.

Coyotes are one of the most vocal animals of the wild. Through a series of howls, yelps and barks, coyotes communicate to other coyotes in the area, with others in their pack, and with their young.

Studies of the coyote's breeding patterns have shown that they are able to control their own population. To do this the coyote relies upon various breeding strategies. If there are too many coyotes for the food supply, they will continue to mate and have young, but only enough pups will be born and will survive to replace those that have died. However, if they are not being overhunted and if there is plenty of food, there will be more pups born in each litter and the number that will survive into adulthood will increase.

Because of this innate ability to vary their own populations, coyotes have thrived and play a central role in maintaining the overall ecological balance. Extensive studies of the coyote have shown the crucial interaction between them and many other species, both predator and prey. When the jackrabbit population decreases, as it does periodically in the Curlew Valley of Idaho and Utah for example, the coyote population decreases also, usually within the following year. Then, when the jackrabbit population increases again, coyotes become more numerous also.

Coyotes mate for life and the adults breed between January and March. The female maintains the den that she selects from an old badger or woodchuck hole, or a natural cavity in the ground. The female carries her young for over two months, giving birth in April or May. A litter may have from two to 12 pups.

Both parents play an active role in raising the pups. At three weeks old the pups are allowed to leave the den to play and by 12 weeks old they are taught to hunt. The family stays together through the summer but by fall the pups will leave to find their own territories. The survival rate for these pups is low. Between 50 and 70% die before they reach adulthood. Eighty percent of those deaths are due to man.

Coyotes limit the populations of various smaller predators, by preying upon them directly or by competing with them for prey. This in turn indirectly affects various prey communities, especially those of birds. When there are no coyotes to keep them in check, the smaller predators expand and are able to kill off a larger segment of the various bird populations.

The coyote and the deer populations interact in an important way as well. Whenever the coyote population decreases, the deer population, particularly that of the white-tailed deer, increases, leading to unhealthy herds and, according to some biologists, to an increase in Lyme disease-bearing ticks in some regions. Coyotes are thus a major factor in maintaining healthy deer populations and in preventing the spread of a disease that is dangerous and potentially fatal to humans.

A coyote. (© U. S. Fish & Wildlife Service. Reproduced by permission.)

Coyotes affect humans more directly as well, especially through their impact upon domestic animals. Since Europeans first came to North America, coyotes have preyed upon sheep and other livestock, costing sheep growers, farmers, and ranchers untold millions of dollars. In some areas, livestock may make up 14% of a coyote's diet. This has prompted extensive **hunting** to control the number of coyotes that ranchers and farmers view as pests. Some ranchers keep guard dogs to protect their livestock. New technology, using inaudible ultrasonic sound, also allows ranchers to detect or repel coyotes.

Although there are no documented cases of humans dying from coyote attacks, coyotes will fiercely defend themselves if cornered. However, they are much less dangerous than wild domestic dogs, which have killed more than 300 people in the decade since 1990. Coyotes can coexist with humans. But can people learn to live with them? Humans cause 90% of all adult coyote deaths by hunting, **trapping**, **poisoning**, and **automobile** accidents. Wolves, black bears, mountain lions, and eagles, as well as various **parasites** and diseases, account for the rest.

Criteria pollutant

Criteria pollutants are air pollutants which, at certain levels of exposure, do not threaten human health and meet National Ambient Air Quality Standards. There are two types of standards for such pollutants. National primary ambient **air quality** standards are levels of air quality with a margin of safety adequate to protect public health. National secondary ambient air quality standards are levels of air quality which are necessary to protect the public welfare from any known or anticipated adverse effects of a pollutant. *See also* Air Quality Control Region; Air quality criteria; Primary standards; Secondary standards

Critical habitat

As institutionalized in the U. S. **Endangered Species Act** of 1973, critical **habitat** is considered the area necessary to the survival of a **species**, and, in the case of endangered and threatened species, essential to their recovery. An animal's habitat includes not only the area where it lives, but also its breeding and feeding grounds, seasonal ranges, and **migration** routes. Critical habitat usually refers to the area that is essential for a minimal viable population to survive and reproduce. The **Endangered Species** Act is intended to conserve "the ecosystems upon which endangered species and threatened species depend." Thus, the Secretary of the Interior is required to identify and designate critical habitats for species that are listed as endangered or threatened under this law. In some cases, areas may be excluded from such designations if the economic, social, or other costs exceed the **conservation** benefits.

The listing of imperiled species and the designation of their critical habitats have become politically sensitive, since these actions can profoundly affect the development and exploitation of areas so designated, and can, under some circumstances, limit such activities as gas and **oil drilling**, timber cutting, dam building, mineral exploration and mining. For this and other reasons, the Department of the Interior often has been reluctant to list certain species, and has excluded species from the protected lists in order not to inconvenience certain commercial interests.

Section 7 of the Endangered Species Act requires all federal agencies and departments to ensure that the activities they carry out, fund, or authorize do not jeopardize the continued existence of listed species or adversely modify or destroy their critical habitat. This provision has proven especially significant, since federal agencies such as the **Forest Service**, **Bureau of Land Management**, and **Fish and Wildlife Service** control vast areas of land that constitute habitat for many listed species and on which a variety of commercial activities, such as **logging** or mining, are undertaken with federal permits.

However, Section 7 of the Endangered Species Act has been implemented in such a way as to generally not affect economic development. The U. S. Fish and Wildlife Service (and, in the case of marine species, the National Marine Fisheries Service) is directed to consult with other federal agencies and review the effects of their actions on listed species. According to a study by the **National Wildlife Federation**, over 99% of the more than 120,000 reviews or consultations conducted between 1979 and 1991 found that no jeopardy to a listed species was involved. In some cases, "economic and technologically feasible" alternatives and modifications, in the words of the act, were suggested that allowed the federal activities to proceed. In only 34 cases were projects cancelled because of threats to listed species. In rare situations, where the conflict between a project and the Endangered Species Act are absolutely irreconcilable, an agency can apply for an exemption from a seven-member Endangered Species Committee.

The earliest major conflict over critical habitat under the Act was the famous 1979 fight over construction of the

$116 million **Tellico Dam** in Tennessee, which would have flooded and destroyed several hundred family farms as well as what was then the only known habitat of a species of minnow, the **snail darter** (*Percina tanasi*). (Since then, snail darters have been found in other areas.) Congress exempted this project from the provisions of the Endangered Species Act, and the dam was built as planned, although many consider it a political boondoggle and a huge waste of taxpayers' money.

More recently, efforts by environmentalists to save the remnants of **old-growth forest** in the Pacific Northwest to preserve habitat for the **northern spotted owl** (*Strix occidentalis caurina*) created tremendous controversy. Thousands of acres of federally-owned forests in Oregon, Washington, and California were placed off-limits to logging, costing jobs in the timber industry in those states. However, conservationists pointed out, if the federal government allowed the last of the ancient forests to be logged, timber jobs would disappear anyway, along with these unique ecosystems and several species dependent upon them. In mid-1993, Interior Secretary announced a compromise decision that allows logging of some ancient forests to continue, but also greatly decreases the areas open to this activity. As natural areas and wildlife habitat continue to be destroyed and degraded, conflicts and controversy over saving critical habitats for listed endangered and threatened species can be expected to continue.

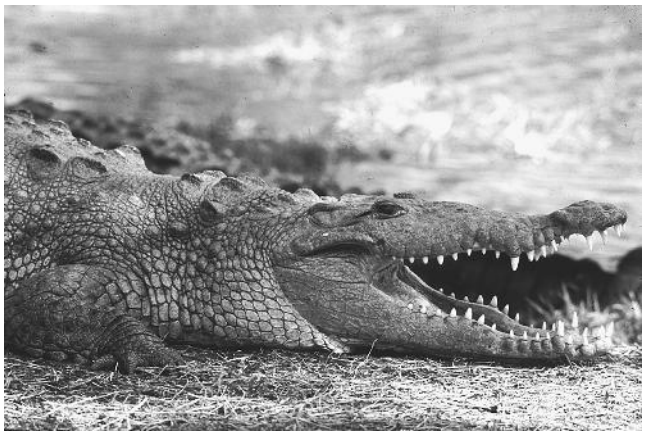
Crocodiles

The largest of the living reptiles, crocodiles inhabit shallow coastal bodies of water in tropical areas throughout the world, and they are often seen floating log-like in the water with only their eyes and nostrils showing. Crocodiles have long been hunted for their hides, and almost all **species** of crocodilians are now considered to be in danger of **extinction**. Members of the crocodile family, called crocodilians (Crocodylidae), are similar in appearance and include crocodiles, alligators, caimans, and gavials. A crocodile can usually be distinguished from an alligator by its pointed snout (an alligator's is rounded), and by the visible fourth tooth on either side of its snout that protrudes when the jaw is shut.

Crocodiles prey on fish, turtles, birds, crabs, small mammals, and any other animals they can catch, including dogs and occasional humans. They hide at the shore of rivers and water holes and grab an animal as it comes to drink, seizing a leg or muzzle, dragging the prey underwater, and holding it there until it drowns. When seizing larger animals, a crocodile will thrash and spin rapidly in the water and tear its prey to pieces. After eating its fill, a crocodile may crawl ashore to warm itself and digest its food, basking in the sun in its classic "grinning" pose, with its jaws wide open, often allowing a sandpiper or plover to pick and clean its teeth by scavenging meat and **parasites** from between them.



The important role that crocodiles play in the **balance of nature** is not fully known or appreciated, but, like all major predators, their place in the ecological chain is a crucial one. They eat many poisonous water snakes, and during times of **drought**, they dig water holes, thus providing water, food, and **habitat** for fish, birds, and other creatures. When crocodiles were eliminated from lakes and rivers in parts of Africa and **Australia**, many of the food fish also declined or disappeared. It is thought that this may have occurred because crocodiles feed on predatory and scavenging species of fish that are not eaten by local people, and when left unchecked, these fish multiplied out of control and crowded out or consumed many of the food fish.

Crocodiles reproduce by laying eggs and burying them in the sand or hiding them in nests concealed in vegetation. Recent studies of the Nile and American crocodiles show that some of these reptiles can be attentive parents. According to these studies, the mother crocodile carefully watches over the nest until it is time for the eggs to hatch. Then she digs the eggs out and gently removes the young from the shells. After gathering the newborns together, she puts them in her mouth and carries them to the water and releases them, watching over them for some time. American crocodiles are very shy and reclusive, and disturbance during this critical period can disrupt the reproductive process and prevent successful hatchings.

In recent decades, crocodiles and other crocodilians have been intensively hunted for their scaly hides, which are used to make shoes, belts, handbags, wallets, and other fashion products. As a result, they have disappeared or have become rare in most of their former habitats. As of 2001, 12 crocodile species have been designated endangered. These species are found in Africa, the Caribbean, Central and South America, the Middle East, the Philippines, Australia, some Pacific Islands, southeast Asia, the Malay Peninsula, Sri Lanka, and Iran. They are endangered primarily due to overexploitation and habitat loss.

The American crocodile (*Crocodylus acutus*) occurs all along the Caribbean coast, including the shores of Central America, Colombia, Cuba, Hispaniola, Jamaica, Mexico,

extreme south Florida, and on the Pacific coast, from Peru north to southern Mexico. The United States population of the American crocodile consists of some 500–1,2000 individuals. This species breeds only in the southern part of **Everglades National Park**, mainly Florida Bay, and perhaps on nearby Key Largo, and at Florida Power and Light Company's Turkey Point plant, located south of Miami. The population is thought to be extremely vulnerable and declining, mainly due to human disturbance, habitat loss (from urbanization, especially real estate development), and direct killing such as on highways and in fishing nets. Predation of hatchlings in Florida Bay mainly by raccoons may also be a factor in the species' decline.

William Cronon (1954 –)

American Frederick Jackson Turner Professor of History, Geography, and Environmental Studies, University of Wisconsin

William Cronon is an environmental historian, and the author of several notable books on **wilderness**, American landscape, and history. Cronon grew up in Madison, Wisconsin and did his undergraduate work at the University of Wisconsin. He won a Rhodes scholarship and spent two years studying at Oxford University, earning a doctorate. His first book, *Changes in the Land: Indians, Colonists and the Ecology of New England*, was published in 1983. This book was cited by reviewer Jim Miller in *Newsweek* as an "eloquent book" with "the rigor of first-rate history and the power of a tragedy." The book's tragic power lies in its subject-the destruction of the fertile **habitat** of pre-colonial New England by the colonists' farming methods and exploitation of **natural resources**, and the virtual eradication of the native American population by diseases brought from Europe by the colonists. Cronon supports his explication of this devastation with evidence gathered from such sources as original Puritan documents and the literature of **ecology** and anthropology. His next book was *Nature's Metropolis: Chicago and the Great West*, published in 1991. This work extended Cronon's investigation of the way human beings shape landscape, looking at relationships between nineteenth century Chicago and the land around it.

Cronon left a tenured position at Yale in order to take up a post at the University of Wisconsin in 1992, returning to his home town. He put out several more books in the 1990s, including *Under an Open Sky: Rethinking America's Western Past*, and *Uncommon Ground: Rethinking the Human Place in Nature*, and editing a book of John Muir's **nature** writings. Cronon's writings have challenged other environmentalists' conception of wilderness as a pristine place untouched by man. His work focuses on the inextricable relationship between human civilization and nature. Idealizing wilderness as something apart from humankind for Cronon stands in the way of clear thinking about how to preserve the **environment**. For example Cronon wrote about the **Arctic National Wildlife Refuge** in 2001, when the incoming Bush administration sparked renewed calls to drill for oil in the nature preserve. Cronon argued that the word wilderness conjured up for most people a "place remote from human settlements, untouched by human hands." The Arctic **National Wildlife Refuge** was in fact deeply tied to human civilization as a holy place to Alaskan Indians, a breeding ground for their caribou, and a migratory stop for birds found in 49 out of 50 states in the U.S. The Alaskan wilderness was neither as empty nor as distant as it seemed. Pointing out the many complex relationships between human communities and the land surrounding them is the core of Cronon's work.

Cross-Florida Barge Canal

The subject of long and acrimonious debate, this attempt to build a canal across the Florida peninsula began in the 1930s and finally expired in 1990. Although it receives little attention today, the Cross-Florida Barge Canal stands as a landmark because it was one of the early cases in which the **Army Corps of Engineers**, whose primary mission has traditionally been to re-design and alter natural waterways, yielded to environmental pressure. The canal's stated purpose, aside from bringing public works funding to the state, was to shorten the shipping distances from the East Coast to the Gulf of Mexico by bypassing the long water route around the tip of Florida. Rerouting barge traffic would also bring commerce into Florida, directing trade and transshipment operations through Floridian hands. An additional supporting argument that persisted into the 1980s was that the existing sea route brought American commerce dangerously close to threatening Cuban naval forces.

Construction on the canal began in 1964, on a route running from the St. Johns River near Jacksonville west to the Gulf of Mexico at Yankeetown, Florida. Canal project plans included three **dams**, five locks, and 110 mi (177 km) of channel 150 ft (46 m) wide and 12 ft (3. 6 m) deep. Twenty-five miles (40 km) of this waterway, along with three locks and three dams, were complete by 1971 when President Richard Nixon, citing economic inefficiency and unacceptable environmental risks, stopped the project by executive order.

From start to finish, the canal's proponents defended the project on economic grounds. The Cross-Florida Canal was proposed as a depression-era job development program. After completion, commerce and recreational fishing would boost the state economy. The Army Corps, well-funded and actively remodelling **nature** in the 1950s and 1960s, took on the project, vastly overestimating economic benefits and essentially dismissing environmental liabilities with the argument that even modest economic gain justified any **habitat** or water loss. After work had begun, further studies concluded that most of the canal's minimal benefits would go to non-Floridian agencies and that environmental dangers were greater than first anticipated. Outcry over environmental costs eventually led to a reappraisal of economic benefits, and the state government rallied behind efforts to halt the canal.

Environmental risks were grave. Although Florida has more **wetlands** than any other state except Alaska, many of the peninsula's natural wetland and riparian habitats had already been lost to development, **drainage**, and channelization. Along the canal route these habitats sheltered a rich community of migratory and resident birds, crustaceans, fish, and mammals. Fifteen **endangered species**, including the red-cockaded woodpecker (*Picoides borealis*) and the Florida manatee, stood to loose habitat to channelized rivers and barge traffic. Specialized spring-dwelling mussels and shrimp that depend on reliable and pure water supplies in this porous limestone country were also threatened.

Most serious of all dangers was that to the Floridan **aquifer**, located in northern Florida but delivering water to cities and wetlands far to the south. Like most of Florida, the reach between Jacksonville and Yankeetown consists of extremely porous limestone full of **sinkholes**, springs, and underground channels. The local **water table** is high, often within a few feet of the ground surface, and currents within the aquifer can carry water hundreds of meters or more in a single day. Because the canal route was to cut through 28 mi (45 km) of the Floridan aquifer's **recharge zone**, the area in which water enters the aquifer, any pollutants escaping from barges would disperse through the aquifer with alarming speed. Even a small fuel leak could contaminate millions of gallons of drinking-quality water. In addition, a canal would expose the aquifer to extensive urban and **agricultural pollution** from the surrounding region.

Water loss presented another serious worry. A channel sliced through the aquifer would allow water to drain out into the sea, instead of remaining underground. Evaporation losses from impounded lakes were expected to reach or exceed 40 million gallons of fresh water every day. With water losses at such a rate, water tables would fall, and salt water intrusions into the fresh water aquifer would be highly probable. In 1985, 95% of all Floridians depended on **groundwater** for home and industrial use. The state could ill afford the losses associated with the canal.

Florida water management districts joined environmentalists in opposing the canal. By the mid-1980s the state government, eager to reclaim idle land easements for development, sale, and extension of the Ocala **National Forest**, put its weight against the Corps and a few local development agencies that had been resisting deauthorization for almost 20 years. In 1990 the United States Congress voted to divide and sell the land, effectively eliminating all possibility of completing the canal.

Paul J. Cruzen (1933 –)

Dutch Meteorologist

Paul Crutzen is one of the world's leading researchers in mapping the chemical mechanisms that affect the **ozone** layer. He has pioneered research on the formation and depletion of the ozone layer and threats placed upon it by industrial society. Crutzen has discovered, for example, that **nitrogen oxides** accelerate the rate of ozone depletion. He has also found that **chemicals** released by bacteria in the **soil** affect the thickness of the ozone layer. For these discoveries he has received the 1995 Nobel Prize in Chemistry, along with Mario Molina and Sherwood Rowland for their separate discoveries related to the ozone and how **chlorofluorocarbons** (CFCs) deplete the ozone layer. According to Royal Swedish Academy of Science, "by explaining the chemical mechanisms that affect the thickness of the ozone layer, the three researchers have contributed to our salvation from a global environmental problem that could have catastrophic consequences."

Paul Josef Crutzen was born December 3, 1933, to Josef C. Crutzen and Anna Gurek in Amsterdam. Despite growing up in a poor family in Nazi-occupied Holland during 1940–1945, he was nominated to attend high school at a time when not all children were accepted into high school. He liked to play soccer in the warm months and ice skate 50–60 mi (80–97 km) a day in the winter. Because he was unable to afford an education at a university, he attended a two-year college in Amsterdam. After graduating with a civil engineering degree in 1954, he designed bridges and homes.

Crutzen met his wife, Tertu Soininen, while on vacation in Switzerland in 1954. They later moved to Sweden where he got a job as a computer programmer for the Institute of **Meteorology** and the University of Stockholm. He started to focus on atmospheric chemistry rather than mathematics because he had lost interest in math and did not want to spend long hours in a lab, especially after the birth of his two daughters, Illona and Sylvia. Despite his busy schedule, Crutzen obtained his doctoral degree in Meteorology at Stockholm University at the age of 35.

Crutzen's main research focused on the ozone, a bluish, irritating gas with a strong odor. The ozone is a molecule made up of three oxygen atoms (O_3) and is formed naturally in the **atmosphere** by a **photochemical reaction**. The ozone begins approximately 10 mi (16 km) above Earth's surface, reaching between 20–30 miles (32–48 km) in height, and acts as a protective layer that absorbs high-energy **ultraviolet radiation** given off by the sun.

In 1970 Crutzen found that soil **microbes** were excreting **nitrous oxide** gas, which rises to the **stratosphere** and is converted by sunlight to nitric oxide and **nitrogen** dioxide. He determined that these two gases were part of what caused the depletion of the ozone. This discovery revolutionized the study of the ozone and encouraged a surge of research on global biogeochemical cycles.

In 1977, while he was the director of the National Center for Atmospheric Research (NCAR) in Boulder, Colorado, Crutzen studied the effects of burning trees and brush in the fields of Brazil. Every year farmers cleared the forests by burning everything in sight. The theory at the time was that this burning caused more **carbon** compounds or trace gases and **carbon monoxide** to enter the atmosphere. These gases were believed to cause the **greenhouse effect**, or a warming of the atmosphere. Crutzen collected and examined this **smoke** in Brazil and discovered that the complete opposite was occurring. He stated in *Discover* magazine: "Before the industry got started the tropical burning was actually decreasing the amount of **carbon dioxide** in the atmosphere." The study of smoke in Brazil led Crutzen to further examine what effects larger amounts of different kinds of smoke might have on the **environment**, such as smoke from a nuclear war.

The journal *Ambio* commissioned Crutzen and John Birks, his colleague from the University of Colorado, to investigate what effects nuclear war might have on the planet. Crutzen and Birks studied a simulated worldwide nuclear war. They theorized that the black carbon soot from the raging fires would absorb as much as 99% of the sunlight. This lack of sunlight, coined "nuclear inter," would be devastating to all forms of life. For this theory Crutzen was named "Scientist of the Year" by *Discover* magazine in 1984 and awarded the prestigious Tyler Award four years later.

As a result of the discoveries by Crutzen and other environmental scientists, a very crucial international treaty was established in 1987. The Montreal Protocol was negotiated under the auspices of the United Nations and signed by 70 countries to slowly phase out the production of chlorofluorocarbons and other ozone-damaging chemicals by the year 2000. However, the United States had ended the production of CFCs five years earlier, in 1995. According to the

New York Times, "the **National Oceanic and Atmospheric Administration** reported in 1994, while ozone over the South Pole is still decreasing, the depletion appears to be leveling off." Even though the ban has been established, existing CFCs will continue to reach the ozone, so the depletion will continue for some years. The full recovery of the ozone is not expected for at least 100 years.

From 1977–80, Crutzen was director of the Air Quality Division, National Center for Atmospheric Research (NCAR), located in Boulder, Colorado. While at NCAR, he located he taught classes at Colorado State University in the department of Atmospheric Sciences. Since 1980 he has been a member of the Max Planck Society for the Advancement of Science, and he is the director of the Atmospheric Chemistry division at Max Planck Institute for Chemistry. In addition to Crutzen's position at the institute, he is a part-time professor at Scripps Institution of Oceanography at the University of California. In 1995 he was the recipient of the United Nations Environmental Ozone Award for outstanding contribution to the protection of the ozone layer. Crutzen has co-authored and edited several books, as well as having published several hundred articles in specialized publications.

Cryptosporidium

Cryptosporidium is a microscopic protozoan parasite that is a significant cause of diarrheal disease (cryptosporidiosis) in humans and animals, including ruminants, swine, cats, and dogs. The word cryptosporidium means hidden spore, referring to the ease with which it can escape detection in environmental samples. Most cryptosporidiosis appears to be caused by the **species** *Cryptosporidium parvum*. The dormant and resistant forms of *Cryptosporidium*, referred to as oocysts, are excreted in the feces of infected humans and animals and can survive under a wide range of environmental conditions. Cryptosporidiosis had long been recognized as a veterinary problem, especially in young farm animals, but was only recognized as a cause of human disease in 1976, when it was diagnosed in animal handlers.

The most common symptom of cryptosporidiosis is watery diarrhea. Other symptoms may include abdominal cramps, nausea, low-grade fever, dehydration, and weight loss. Symptoms usually develop four to six days after infection, but may occur from two to 10 days after infection. In individuals with healthy, normal immune systems, the disease usually only lasts for several days, and rarely more than two weeks. Some infected persons may not even become ill, while others become ill, seem to recover, but become ill again. Infected persons may shed oocysts in their feces for months, even when they are not exhibiting disease symptoms.

Cryptosporidiosis can cause complications in persons with diabetes, alcoholism, or pregnancy. Diarrhea and dehydration can severely affect the very young, the elderly, and the frail. Cryptosporidiosis can be prolonged and life-threatening in immuno-compromised individuals (those who have weak immune systems), such as transplant patients, people infected with the Human Immunodeficiency **Virus** (HIV) (which causes Acquired Immuno-Deficiency Syndrome [AIDS]), **cancer** patients on chemotherapy, and persons who are taking medications that suppress the immune system. By 1983, the number of infections in humans was increasing as the **AIDS** epidemic began; also diagnostic methods were developed to identify the parasite in stool samples, which aided in the identification and documentation of the disease.

In industrialized nations, about 0.4% of the population passes oocysts in the feces at any one time, while about 2–2.5% of patients admitted to hospitals are passing oocysts. About 30–35% of the United States population have antibodies in their blood to *Cryptosporidium*. In developing nations, the prevalence is higher, where up to 60–70% of people have circulating antibodies in their blood to *Cryptosporidium*. In AIDS patients, the numbers of individuals with chronic cryptosporidiosis is about 10% in industrialized nations and up to 40% in some developing nations.

Cryptosporidiosis cannot be diagnosed by symptoms alone, but must be confirmed with a specific diagnostic stool test for the parasite. There is no drug available to cure cryptosporidiosis. Symptoms are treated with anti-diarrheal medicines and fluids to prevent dehydration. People with strong immune systems will recover on their own and may develop limited immunity to recurring infections.

A person can become infected with *Cryptosporidium* by ingesting anything that has been in contact with feces from an infected person or animal. Hands can become contaminated with *Cryptosporidium* through person-to-person contact, such as changing of a child's diaper, caring for someone with diarrhea, or touching a part of the body contaminated with feces. Cryptosporidiosis is easily spread through social groups, such as families, day care centers, and

nursing homes. Persons who work with animals or touch soils or objects contaminated with feces can contract cryptosporidiosis.

Infection with *Cryptosporidium* can also occur by drinking water that is contaminated with oocysts. The first report of spread of cryptosporidiosis through a municipal drinking water system was in 1987 in Carrollton, Georgia, where 13,000 people, out of a total population of 65,000, became ill. In 1993, a municipal drinking water system in Milwaukee, Wisconsin, became contaminated with *Cryptosporidium*, and 400,000 people became ill. Four thousand people were hospitalized, at a cost of $54 million, and 100 people died, including some persons with AIDS. Both water systems had met all state and drinking water standards. There have also been more than a dozen outbreaks reported in the United Kingdom. These outbreaks demonstrated the risks of waterborne cryptosporidiosis, for unfortunately *Cryptosporidium* oocysts are resistant to many environmental stresses and chemical disinfectants such as **chlorine** that are used in municipal drinking water systems and swimming pools (swallowing a small amount of water while swimming in a chlorinated pool can cause cryptosporidiosis). The mechanism that protects oocysts from **chlorination** has not yet been positively identified—the oocyst membrane may be protective, or an oocyst may pump **toxins** from its cell before the toxins can cause harm.

Oocysts are present in most surface bodies of water in the United States, many of which are sources of public drinking water. They become more prevalent during periods of **runoff** (generally from March-June during spring rains in North America) or when **wastewater** treatment plants become overloaded or break down. Properly drilled and maintained **groundwater wells**, with intact well casings, proper **seals**, and above-ground caps, are not likely to contain *Cryptosporidium* because of natural **filtration** through **soil** and **aquifer** materials.

The detection of *Cryptosporidium* oocysts is unreliable, for recovery and enumeration of oocysts from water samples is difficult. Concentration techniques for oocysts in water samples are poor, and detection methods often measure algae and other debris in addition to oocysts. The volume of water required to concentrate oocysts for detection can range from 26–264 gal (100–1,000 l). Determination of whether oocysts are infective and viable or a member of the species that causes disease is not easy to accomplish. The development of more accurate, rapid and improved assays for oocysts is required, for present tests are time-consuming, highly subjective, and dependent on the skills of the analyst.

In addition, the number of oocysts (the effective dose) required to cause cryptosporidiosis has not yet been well-defined and requires more investigation. Studies to date have suggested that the 50% infectious dose may be around 132 oocysts, and in some cases, as few as 30 oocysts (infections have also occurred with the ingestion of a single oocyst). Human susceptibility to *Cryptosporidium* likely varies between individuals and between various *Cryptosporidium* strains.

Therefore protection of drinking water supplies from contamination by *Cryptosporidium* requires multiple approaches. Filtration of drinking water supplies is the only reliable conventional treatment method. Water in a treatment plant is mixed with coagulants that aid in the settling of particles in water; removal can be enhanced by using sand filtration. **Ozone** disinfection can kill *Cryptosporidium* but ozone does not leave a residual in the distribution system as chlorine does, which provides protection of treated water to the point of use but does not neessarily kill *Cryptosporidium* anyway.

Watershed protection to prevent contamination from entering water sources is also important in protection of drinking water supplies. Regulation of septic systems and **best management practices** can be used to control runoff of human and animal wastes.

An individual can also take steps to ensure that drinking water is safe. Boiling water (bringing water to a rolling boil for at least one minute) is the best way to kill *Cryptosporidium*. After boiling, the water should be stored in the refrigerator in a clean bottle or pitcher with lid; care should be taken to avoid touching the inside of the bottle or lid to prevent re-contamination. Point-of-use **filters**, either attached to a faucet, or the pour-through type, can also be used to remove *Cryptosporidium* from water. Only filters with an absolute, rather than a nominal, pore size of one micron or smaller should be used to remove oocysts. Reverse osmosis filters are also effective. Lists of filters and reverse osmosis filters that will remove *Cryptosporidium* oocysts can be obtained from NSF International, an independent nonprofit testing agency.

The use of bottled water is not necessarily safer than tap water, as water from a surface water source has the same risks of containing oocysts as tap water from that source, unless it has been treated with appropriate treatment technologies, such as distillation, pasteurization, reverse osmosis, or filtration with an absolute one micron rating, before bottling. Bottled water from deep groundwater wells has a low likelihood of being contaminated with oocysts, so the labels on water bottles should be examined before use to determine water source and treatment methods.

Food can also be a source of *Cryptosporidium*. In 1996, in the Northeastern United States, unpasteurized apple cider and juice was associated with *Cryptosporidium* infections. In 1997, in Spokane, Washington, members of a group attending a dinner banquet become ill with cryptosporidiosis. The parasite may be present in uncooked or unwashed fruits

and vegetables that are grown in areas where manure was used or animals were grazed or in beverages or ice prepared with contaminated water. Pasteurization of dairy products will kill oocysts. Bottled and canned drinks, such as soda and beer, are usually heated and/or filtered sufficiently to kill or remove *Cryptosporidium* oocysts. Care should be taken to wash hands thoroughly with soap and water before eating, preparing or serving food. Fruits and vegetables that will be eaten raw should be washed or peeled before being eaten. When traveling to areas with poor **sanitation**, extra care should be taken in the selection of food and drink.

Cubatao, Brazil

Once called the "valley of death" and the "most polluted place on earth," Cubatao, Brazil, is a symbol both of severe **environmental degradation** and how people can work together to clean up their **environment**. A determined effort to reduce **pollution** and restore the badly contaminated air and water in the past decade has had promising results. While not ideal by any means, Cubatao is no longer among the worst places in the world to live.

Cubatao is located in the state of São Paulo, near the Atlantic coastal city of Santos, just at the base of the high plateau on which São Paulo—Brazil's largest city—sprawls. Thirty years ago, Cubatao was an agreeable, well-situated town. Overlooking Santos Bay with forest-covered mountain slopes rising on three sides around it, Cubatao was well removed from the frantic hustle and bustle of São Paulo on the hills above. Several pleasant little rivers ran through the valley and down to the sea. When the rivers were dammed to generate electricity in the early 1970s, however, the situation changed.

Cheap energy and the good location between São Paulo and the port of Santos attracted industry to Cubatao. An oil refinery, a steel mill, a **fertilizer** plant, and several chemical factories crowded into the valley, while workers and job-seekers scrambled to build huts on the hillsides and the swampy lowlands between the factories. With almost no **pollution control** enforcement, industrial smokestacks belched clouds of dust and toxic effluents into the air while raw sewage and chemical waste poisoned the river. By 1981, the city had 80,000 inhabitants and accounted for 3% of Brazil's industrial output. It was called the most polluted place in the world. More than 1,000 tons of toxic gases were released into the air every day. The steaming rivers seethed with multi-hued chemical slicks, foamy suds, and debris. No birds flew in the air above, and the hills were covered with dying trees and the scars of **erosion** where rains washed dirt down into the valley.

Sulfur dioxide, which damages lungs, eats away building materials, and kills vegetation, was six times higher than World Health Organization guidelines. After a few hours exposure to sunlight and water vapor, sulfur oxides turn into sulfuric **acid**, a powerful and dangerous corrosive agent. Winter air inversions would trap the noxious gases in the valley for days on end. One quarter of all emergency medical calls were related to respiratory ailments. Miscarriages, stillbirths, and deformities rose dramatically. The town was practically uninhabitable.

The situation changed dramatically in the mid-1980s, however. Restoration of democracy allowed citizens to organize to bring about change. Governor Franco Montoro was elected on promises to do something about pollution, and

his administration came through on campaign promises. Between 1983 and 1987, the government worked with industry to enforce pollution laws and to share the costs of clean-up. Backed by a **World Bank** loan of $100 million, the state and private industry invested more than $200 million for pollution control. By 1988, 250 out of 320 pollution sources were reduced or eliminated. Ammonia releases were lowered by 97%, **particulate** emissions were reduced 92%, and sulfur dioxide releases were cut 84%. Ozone-producing **hydrocarbons** and volatile organic compounds dropped nearly 80%. The air was breathable again. Vegetation began to return to the hillsides around the valley, and birds were seen once more.

Water quality also improved. Dumping of trash and industrial wastes was cut from some 64 metric tons per day to less than 6 tons. Some 780,000 tons of **sediment** were dredged out of the river bottoms to remove toxic contaminants and to improve water flow. Fish returned to the rivers after a 20-year absence. Reforestation projects are replanting native trees on hillsides where mudslides threatened the town. The government of Brazil now points to Cubatao with pride as an illustration of its concern for environmental protection. This is a heartening example of what can be done to protect the environment, given knowledge, commitment, and cooperation.

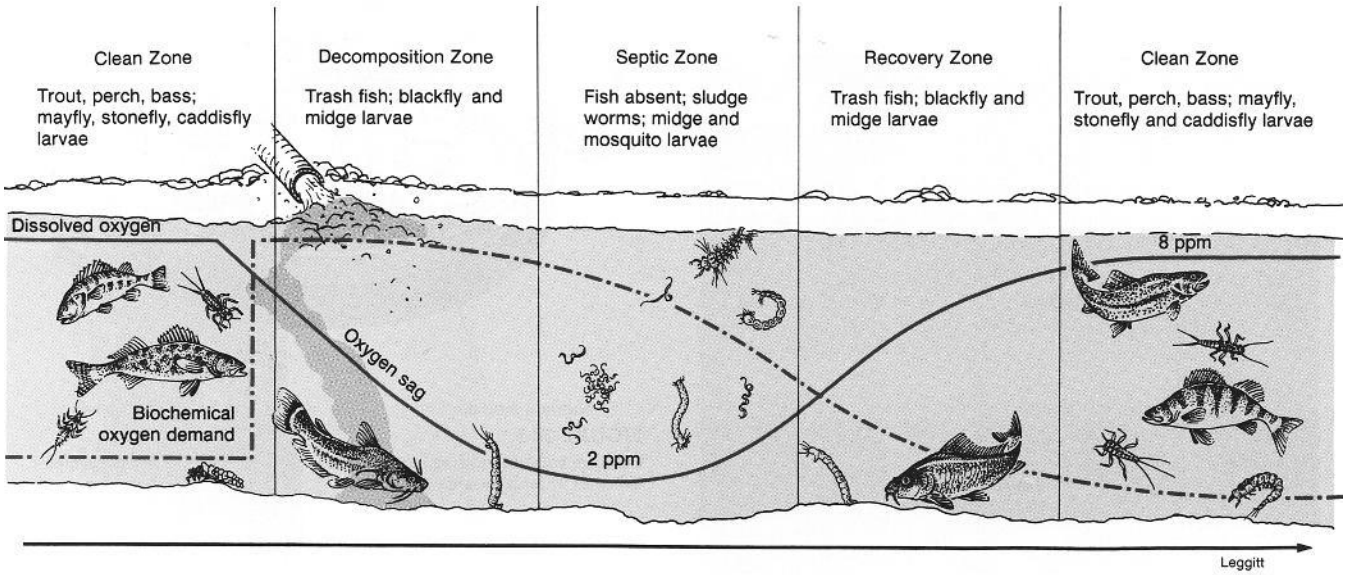
Cultivation

see **Agricultural pollution**

Cultural eutrophication

One of the most important types of **water pollution**, cultural eutrophication describes human-generated fertilization of water bodies. Cultural denotes human involvement, and eutrophication means truly nourished, from the Greek word *eutrophic*. Key factors in cultural eutrophication are **nitrates** and **phosphates**, and the main sources are treated sewage and **runoff** from farms and urban areas. The concept of cultural eutrophication is based on anthropocentric values, where clear water with minimal visible organisms is much preferred over water rich in green algae and other **microorganisms**.



Nitrates and phosphates are the most common limiting factors for organism growth, especially in aquatic ecosystems. Most fertilizers are a combination of **nitrogen**, **phosphorus**, and potassium. Nitrates are key components of the amino acids, **peptides**, and proteins needed by all living organisms. Phosphates are crucial in energy transfer reactions within cells. Natural sources of nitrates (and ammonia) are more readily available than phosphates, so the latter is often cited as the crucial limiting factor in plant growth. Nitrates are supplied in limited quantities by decaying plant material and nitrogen-fixing bacteria, but phosphates must come from animal bones, organic matter, or from the breakdown of phosphate-bearing rocks. Consequently, the introduction and widespread use of phosphate **detergents**, combined with excess **fertilizer** in runoff, has produced a near ecological disaster in some waters.

In ecosystems, there is a continuous cycling of matter, with green algae and plants making food from **chemicals** dissolved in water via **photosynthesis**; this provides the food base needed by herbivores and carnivores. Dead plant material and animals are then decomposed by **aerobic** (oxygen using) and **anaerobic decomposers** into the simple elements they came from. Natural water bodies are usually well-suited for handling this matter cycling; however, human impacts often inject large amounts of additional nutrients into the system, changing them from **oligotrophic** (poorly nourished) to eutrophic water bodies. Once present within a relatively closed body of water, such as a lake or **estuary**, these extra nutrients may cycle numerous times before leaving the system.

Green algae and trashy fish may thrive in eutrophic water, but most people are offended by what they perceive as "scum." Nutrient-poor water is usually clear and possesses a rich supply of oxygen, but as the **nutrient** load increases, oxygen levels drop and turbidity rises. For example, when sewage is dumped into a body of water, the sewage fertilizes the algae, and as they multiply and die the aerobic decomposers multiply in turn. The increased demand for oxygen by the decomposers outstrips the system's ability to provide it. As a result, **dissolved oxygen** levels may fall or sag even below 2.0 **parts per million**, the threshold below which even trashy fish cannot a survive (trout need at least 8.0 ppm to survive). Even though the green algae are producing oxygen as a byproduct of photosynthesis, even more oxygen is consumed by decomposers breaking down the dead algae and other organisms.

As water flows downstream the waste is slowly broken down, so there is less for the decomposers to feed on. Biological oxygen demand slowly falls, while the dissolved oxygen levels rise until the river is finally back to normal levels. Most likely, the nutrients recycled by decomposers are either diluted, turned into **biomass** by trees and consumer organ-

Oxygen sag downstream of a source of organic pollution. (McGraw-Hill Inc. Reproduced by permission.)

isms, or tied up in bottom sediments. Thus a river can naturally cleanse itself of **organic waste** if given sufficient time. Problems arise, however, when discharges are too large and frequent for the river to handle; under extreme conditions it becomes "dead" and is suited only for low-order, often anaerobic, organisms. Municipalities using river water locate their intakes upstream and their **sewage treatment** plants and storm drains downstream. If communities were required to do the reverse, the quality of river water would dramatically improve.

The major sources of nitrates and phosphates in aquatic systems are treated sewage **effluent**; excess fertilizer from farms and urban landscapes; and animal wastes from **feedlots**, pastures, and city streets. In some areas with pristine waters, such as **Lake Tahoe**, tertiary sewage treatment has been added; chemicals are used to reduce nitrate and phosphate levels prior to **discharge**.

Runoff from nonpoint sources is a far more difficult problem because they are harder to control and remediate than runoff from point sources. Point sources can be diverted into treatment plants, but the only feasible way to reduce nonpoint sources is by input reduction or by on-site control. Less fertilizer more frequently applied, especially on urban lawns, for example, would help reduce runoff. Feedlots are a major concern; runoff needs to be collected and treated in the same manner as human sewage; this may also apply to street runoff. Green cattle ponds are a sure sign of the abundant nutrients supplied by these mobile meat factories.

Phosphate detergents are superior cleaning agents than soap, but the resultant **wastewater** is loaded with this key limiting factor. Phosphate levels in detergents have since been reduced, but its impact is so powerful that abatement may require tertiary treatment.

The battle between Oklahoma and Arkansas over Illinois River **pollution** provides a useful case study of the debate over cultural eutrophication. This river has its headwaters in Arkansas and has become a prime tourist attraction in Oklahoma. Enthusiasts come from all over to canoe the river; summer use is especially heavy. However, economic development within the basin has resulted in a steady decline in river quality.

Arkansas started a legal war with Oklahoma when it sought and obtained **Environmental Protection Agency**

(EPA) approval to dump half of the treated sewage from a new plant in Fayetteville into a tributary of the Illinois. Arkansas argued that its state-of-the-art treatment plant would produce an effluent having little impact on **water quality** by the time it reached the border. Oklahoma countered that it could not risk the potential economic loss if the river became polluted.

This controversy has had a salutary impact on research into the causes of cultural eutrophication within this basin. Scientists from Oklahoma State University and the University of Arkansas are collaborating on a long-term study of river quality and pollution sources. It is highly likely that nonpoint sources within both states will be identified as the key culprits, especially from livestock operations.

There is one major success story in the battle to overcome the effects of cultural eutrophication. The Thames River in England was devoid of aquatic life for centuries. Now a massive cleanup effort is restoring the river to vitality. Many fish have returned, most notably the pollution-sensitive **salmon**, which had not been seen in London for 300 years. However, much work remains, especially in former Warsaw Pact countries and those in the **Third World**.

Cuyahoga River

This 103-mi (166-km) long tributary of **Lake Erie** is a classic industrial river, with, however, one monumental distinction: it caught fire–twice. The first fire, in 1959, burned for eight days; fireboats merely spread the blaze. Typical of the times, a November 1959 article in *Fortune* seemed to glorify the industrial **pollution** here, with words and a portfolio of drawings reminiscent of Charles Dickens. Inspired by feelings of space and excitement, the artist stated: "It is a great expanse, with a smoky cast over everything, smudged with orange dust from the ore–an overall brown color." Clevelanders consoled themselves that the foul water at least symbolized prosperous times.

The second fire occurred on June 22, 1969, as several miles of river along the lowland industrial section called "the Flats" ignited, fed by bunker oil, trash, and tree limbs trapped by a bridge 6 mi (9.7 km) upstream. This fire, along with the Santa Barbara oil well blowout, provided graphic television images which were projected around the world. Jack A. Seamonds's June 18, 1984 article in *U.S. News & World Report* credited the fire with lighting "the fuse that put the bang in the nationwide campaign to clean up the environment." Pamela Brodie described it in the September-October 1983 issue of *Sierra* as "The most infamous episode of **water pollution** in the U.S...It inspired a song...and the Clean Water Act."

Although the fire badly hurt Cleveland's image, steps were already underway to correct the problem. The city government had declared the river a fire hazard and won voter approval in the autumn of 1968 for major funding to correct sewage problems. After the fire, Cleveland's three image-conscious steel companies voluntarily quit dumping cyanide-laced water and two installed cooling towers. As a result of just these actions alone, the river once again began to freeze in the winter. The city of Akron banned phosphate **detergents**, and eventually won the lawsuits brought against it by soap companies. These and other efforts, plus completion in 1983 of the major **sewage treatment** project, brought about far more encouraging reports.

The Cuyahoga was formerly dumping 155 tons of waste per day, and was even devoid of **sludge** worms. But by 1978, *Business Week* could report substantial improvement: **phosphates** were cut in half; **chemicals** were down 20–40%; and **oil spills** went from 300 per year to 25 in 1977. For the first time, local residents saw ducks on the river. By 1984, **point source** pollution had been largely eliminated. The waterfront was rediscovered, with restaurants and trendy stores where once fires had burned

The water is still light brown, churned up by deep-water shipping, and Lake Erie is still polluted. Nonetheless, the Cuyahoga seems to have been largely redeemed, and thus helped revitalize the city of Cleveland. The river became one of 14 American Heritage rivers in 1998. *See also* Great Lakes; Oil Pollution Act (1990); Water quality

Cyclone collector

A device that removes solids from an **effluent** stream (solid/liquid or solid/gas) using gravitational settling. The input stream enters a vertical tapered cylinder tangentially and spiral fins or grooves cause the stream to swirl. The centrifugal force created by this swirling action causes particles to settle out of the input stream. These solids are concentrated at the walls and move to the bottom of the tapered cone. The solid-free fluid or gas is removed along the center line of the collector via a vortex finder. A **cyclone** collector is a compact device capable of processing large volumes of effluent; however, pressure energy is expended in its operation. It removes particles from the effluent stream less effectively than bag **filters** or **electrostatic precipitation**. *See also* Baghouse

Dam removal

There are over 77,000 **dams** of significant size (over 6 ft [1.8 m] tall) in the United States, and tens of thousands of additional uncharted smaller dam structures. Constructed for the purposes of harnessing **water resources** for **irrigation**, water supply, and hydroelectric power, dams can be a useful ally for human needs; they also have a major and long-term impact on the entire river **ecosystem**.

Since 1912, over 460 dams have been removed from United States waterways for both safety and environmental reasons. Dams associated with hydroelectric power projects are decommissioned after their useful life and removal is often recommended to return river ecosystems back to their natural state.

Damaged or obsolete dam structures may present a safety hazard, particularly if they are no longer regularly maintained. Upkeep of a dam is expensive, and local taxpayers may bear the brunt of caring for a dam that no longer serves any practical function. Finally, abandoned or unused dams can be aesthetically unpleasant in an otherwise scenic natural area.

Dams and their associated reservoirs can significantly impact river ecosystems and alter their natural course. The structures raise water temperatures, obstruct debris and **nutrient** flow, and prevent **sediment** dispersal. And they have an enormous impact on runs of **salmon**, steelhead, and other migratory fish, often in a relatively short period of time. For example, according to the National **Fish and Wildlife Service** the first dam to be built across the Connecticut River in 1798 resulted in the **extinction** of native Atlantic salmon stock in the river just a few years later. Despite the integration of fish lifts and fish ladders into modern dams, populations of native fish stocks are still greatly depleted by dam structures. Currently, several dams in the northwest are being removed to replenish many of these **species** which are protected under the **Endangered Species Act**.

There can be some short-term negative environmental issues associated with dam removal projects. Contaminated sediment that may collect under a dam can disperse throughout the area, and populations of non-native species that have settled in the dam-altered **habitat** may decline once the dam has been removed. However, in most cases dam removal encourages re-establishment of the native ecosystem and organisms.

Depending on its location and the ownership of the dam, removal may be governed by a variety of federal, state, and local authorities. For federal dam projects, the U.S. **Army Corps of Engineers** and/or the **Bureau of Reclamation** are charged with planning and completion of removal projects. However, only 3% of dams included in the U.S. Army Corps of Engineers national inventory of dams are owned by the federal government, compared with 58% of privately-owned dams.

Even if ownership of a dam is private, the waterways the structure harnesses are public and there is still a significant amount of regulatory oversight on all levels of government. The U.S. **Environmental Protection Agency** (EPA) and some state authorities typically request a full environmental assessment and written report called an "Environmental Impact Statement" (or EIS). The EIS outlines different scenarios for completion of a dam removal project, from no action (letting the dam naturally deteriorate over time) to full dismantling and removal with additional clean-up of dam sediments. It then describes the impact each approach will have on the ecosystem surrounding the dam site.

Dams (environmental effects)

Most dams are built to control flood hazards, to store water for **irrigation** or other uses, or to produce electricity. Along with these benefits come environmental costs including riparian **habitat** loss, water loss through evaporation and **seepage**, **erosion**, and declining **water quality**. Farther-reaching consequences of dams include changes in **groundwater** flow and the displacement of human populations.

Riparian, or stream–side, habitats suffer both above and below dams. Valuable ecological zones that support specialized plants, riparian environments, and nearby shallows provide food and breeding grounds for birds, fish, and many other animals. Upstream of a dam, impounded water drowns riparian communities. Because reservoirs can fill hundreds of miles of river channel, and because many rivers have a long sequence of dams and reservoirs, habitat drowning can destroy a great deal of river **biodiversity**. Downstream, shoreline environments dry up because of water diversions (for irrigation or urban use) or because of evaporation and seepage losses in the **reservoir**. In addition, dams interrupt the annual floods that occur naturally on nearly all rivers. Seasonal **flooding** fertilizes and waters flood plains and clears or redistributes debris in river channels. These beneficial effects of flooding cease once a river is dammed.

Dams and reservoirs alter **sediment** deposition in rivers. Most rivers carry large amounts of suspended **silt** and sand, and dams trap sediments normally deposited downstream. Below the dam, erosion reshapes river channels once sediment deposition ceases. If erosion becomes extreme, bridges, levees, and even river deltas can be threatened. Meanwhile, sediment piling up in the still waters of the reservoir behind the dam decrease water storage capacity. An increasingly shallow reservoir also becomes gradually warmer. Oxygen content decreases as the water temperature rises; fish populations fall, and proliferating algae and aquatic plants can begin to block the dam's water intakes. In **arid** regions a higher percentage of river water evaporates as the reservoir becomes shallower. Evaporating water leaves behind salts, which further decrease water quality in the reservoir and river.

Water losses from evaporation can be extreme: Lakes Powell and Mead on the **Colorado River** lose about 3 billion cu ft (1 billion cu m) of water to evaporation each year; Egypt's Lake Nasser, on the Nile River, loses about 45 billion cu ft (15 billion cu m). Water losses also result from seepage into bedrock. As river water enters groundwater, water tables usually rise around a reservoir. In arid regions increased groundwater can increase local fertility (sometimes endangering delicate dry-land plant **species**), but in moister regions excessive groundwater can cause swamping. Evaporation from exposed groundwater can leave higher salt concentrations in the **soil**. The most catastrophic results of reservoir seepage into groundwater occur when saturated rock loses its strength. In such events valley walls can collapse, causing dam failure and disastrous flooding downstream.

Perhaps the most significant environmental effect of dams results from the displacement of human populations. Because people normally settle along rivers, where water for drinking, irrigation, power, and transport are readily available, reservoir flooding can displace huge populations. The planned **Three Gorges Dam** on China's Chang Jiang (Yangtze River) will displace 1.4 million people and flood some of western China's best agricultural land. A series of dams on India's Narmada river will inundate the homes of 1.5 million people along with 600,000 acres (150,000 ha) of farm land. In both cases, people will need to find new places to live and clear new land to grow food. Such ripple effects carry a dam's influence far beyond its immediate proximity.

Where dams are needed for power, they can have a positive effect in offsetting environmental costs associated with other power sources. Hydropower is cleaner and safer than **nuclear power**. Water turbines are also cleaner than coal-fired generators. Furthermore, both nuclear and **coal** power require extensive mining, with environmental costs far more severe than those of even a large dam.

Jay Norwood "Ding" Darling (1876 – 1962)

American environmental cartoonist

Most editorial page cartoonists focus on the tough job of meeting daily deadlines, satisfied that their message will influence public opinion through their drawings. Jay Norwood "Ding" Darling, however, drew Pulitzer prize-winning cartoons, but was also immersed in **conservation** action, emerging as one of the great innovators in the conservation movement of the first half of the twentieth century.

Norwood, Michigan, was Darling's namesake birthplace, but he grew up in Elkhart, Indiana, and attended high school in Sioux City, Iowa, at a time when the area was relatively undeveloped. Wandering the prairies of nineteenth century Iowa, Nebraska, and South Dakota instilled in him a life-long love of the outdoors and **wildlife**.

After an uneven beginning, Darling graduated from Beloit College in Wisconsin with a degree in biology. (At one college, during one semester, biology was the only course he passed). And he was expelled from Beloit for a year for caricaturing individuals in the college faculty and administration. Building on an early interest in sketching (and the cartooning skills developed in college) Darling went on to a half-century of drawing political cartoons, including some of the most memorable conservation/environmental cartoons of the twentieth century. His first job (1900) was as a reporter (and sometimes caricaturist) in Sioux City, but six years later, he was hired by the *Des Moines Register and Leader*, where his primary task was to produce a cartoon each day for the editorial page. He retired from that same paper in 1949. Darling did spend two years as an editorial cartoonist for the *New York Globe*, but returned to Iowa at the first real opportunity.

The only other significant period away from his Des Moines newspaper position illustrates his action mode as a conservationist. Darling was active in political life generally, and this involvement often reflected his love of the outdoors and his dismay at what he felt the United States was doing to destroy its natural resource base. He helped organize the **Izaak Walton League** in Des Moines, was active in the landscaping of local parks, and worked to establish the first cooperative wildlife research unit at Iowa State College in Ames, a unit that served as a model for the establishment of similar units in other states.

Perhaps his greatest impact as an activist resulted from his appointment, by President Franklin Roosevelt, as head of the U.S. Bureau of Biological Survey, predecessor of the U.S. **Fish and Wildlife Service**. He was only in the position for two years, not being happy as a bureaucrat and not happy away from Iowa. But he was reportedly very effective in the job, "raiding" (in Roosevelt's words) the U.S. Treasury for scarce depression-era funds for waterfowl **habitat** restoration, and initiating the duck stamp program which over the years has funded the acquisition of several million acres added to the **National Wildlife Refuge** system. He also used his drawing skills to design the first duck stamp, as well as the flying goose that has become the signpost and symbol of the national **wildlife refuge** system.

Darling was also one of the founders, and then first President of the **National Wildlife Federation** in 1938. He later criticized the organization, and the proliferation of conservation organizations in general, because he first envisioned the Federation as an umbrella for conservation efforts and thought the emergence of too many groups diluted the focus on solving conservation and environmental problems. Until the end of his life, he tried, and failed, to organize a conservation clearing house that would refocus the conservation effort under one heading.

He put into all his efforts lessons of interdependence learned early from biology classes at Beloit College: "Land, water, and vegetation are [interdependent] with one another. Without these primary elements in natural balance, we can have neither fish nor game, wild flowers nor trees, labor nor capital, nor sustaining habitat for humans."

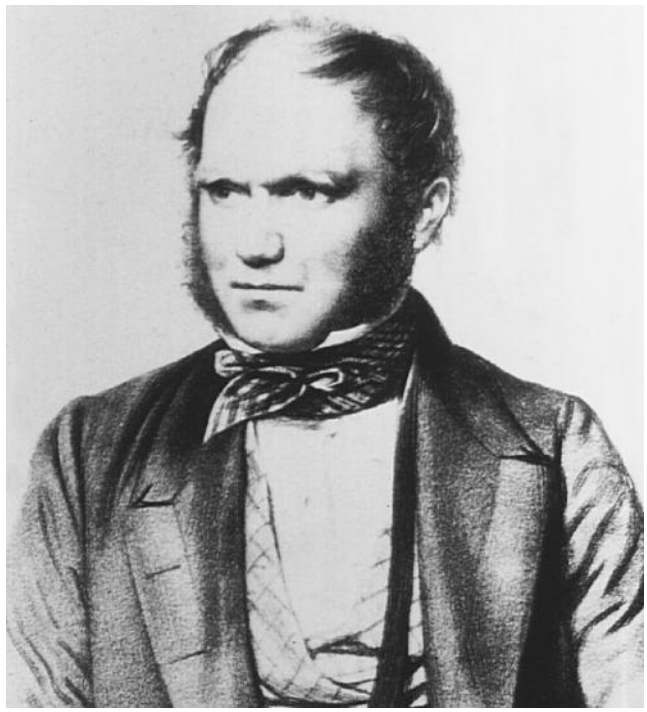
Charles Robert Darwin (1809 – 1882)

English naturalist

Darwin, an English biologist known for his theory of **evolution**, was born at Shrewsbury, England, on February 12, 1809. He was born on the same day and the same year as



Abraham Lincoln, a coincidence that may alert American readers to Darwin's era. He studied, traveled, and published his famous *On the Origin of Species* (1859) just prior to the American Civil War.

Darwin's father was an affluent physician and his mother the daughter of the potter Josiah Wedgwood. Charles married Emma Wedgwood, his first cousin, in 1839. Due to his family's wealth, Darwin was made singularly free to pursue his interest in science.

Darwin entered Edinburgh to study medicine, but, as he described in his autobiography, lectures were "intolerably dull," human anatomy "disgusted" him, and he experienced "nausea" in seeing surgery. He subsequently entered Christ's College, Cambridge, to prepare for Holy Orders in the Church of England. While at Cambridge, Darwin became intensely interested in geology and botany, and because of his knowledge in these sciences he was asked to join the voyage of the HMS *Beagle*. Darwin's experiences during the circumnavigational trek of the Beagle were of seminal importance in his later views on evolution.

Darwin's *On the Origin of Species* is a monumental catalog of evidence that evolution occurs, together with the description of a mechanism that explains such evolution. This "abstract" of his notions on evolution was hurried to publication because of a letter Darwin received from Alfred Russell Wallace expressing similar views. Darwin's evidence for evolution was drawn from comparative anatomy, embryology, distribution of **species**, and the fossil record. He believed that species were not immutable but evolved into other species. But how? His theory of evolution by natural selection is based on the premise that species have a great reproductive capacity. The production of individuals in excess of the number that can survive creates a struggle for survival. Variation between individuals within a species was well documented. The struggle for survival, coupled with variation, led Darwin to postulate that those individuals with favorable variations would have an enhanced survival potential and hence would leave more progeny and this process would lead to new species. This notion is sometimes referred to as "survival of the fittest." While the theory of evolution by natural selection was revolutionary for its day, essentially all biologists in the late twentieth century accept Darwinian evolution as fact.

The first edition of the *Origin* had a printing of 1,250 copies. It sold out the first day. Darwin was an extraordinarily productive author for someone who considered himself to be a slow writer. Among his other books are *Structure and Distribution of Coral Reef* (1842), *Geological Observations on Volcanic Islands* (1844), *On the Various Contrivances by which British and Foreign Orchids are Fertilized by Insects* (1862), *Insectivorous Plants* (1875), and *On the Formation of Vegetable Mould through the Action of Worms* (1881). The last book, of interest to ecologists and gardeners, was published only six months prior to Darwin's death.

Charles Darwin. (Photo Researchers Inc. Reproduced by permission.)

Darwin died at age 73 and is buried next to Sir Isaac Newton at Westminster Abbey in London.

DDT

see **Dichlorodiphenyl-trichloroethane**

Dead zones

The term dead zone refers to those areas in aquatic environments where there is a reduction in the amount of **dissolved oxygen** in the water. The condition is more appropriately

called hypoxia or hypoxic waters or zones. Hypoxia in marine environments is determined when the dissolved oxygen content is less than 2–3 milligrams/liter. Five to eight milligrams/liter of dissolved oxygen is generally accepted as the normal level for most marine life to survive and reproduce. Dead zones can not only reduce the numbers of marine animals, but they can also change the **nature** of the **ecosystem** within the hypoxic zone.

The main cause of oxygen depletion in aquatic environments is eutrophication. This process is a chain of events that begins with **runoff** rich in **nitrogen** and **phosphorus** that makes its way into rivers that eventually **discharge** into estuaries and river deltas. This nutrient-laden water, combined with sunlight, stimulates plant growth, specifically algae, seaweed, and **phytoplankton**. When these plants die and fall to the ocean floor, they are consumed by bacteria that use large amounts of oxygen, thereby depleting the **environment** of oxygen.

Dead zones can lead to significant shifts in **species** balances throughout an ecosystem. Species of aquatic life that can leave these zones—such as fish and shrimp—do so. Bottom-growing plants, shellfish, and others that cannot leave, die, creating an area devoid of aquatic life. This is the reason the term *dead zone* has been aptly used (especially by the media) to describe these areas.

Eutrophication of estuaries and enclosed coastal seas has often been a natural phenomenon when offshore winds and water currents force deep nutrient-laden waters to rise to the surface, stimulating algae bloom. The timing and duration of these conditions varies from year to year and within seasons. Climatic conditions and catastrophic weather events can influence the rapidity hypoxia can occur. In the past, these natural hypoxic areas were limited, and the marine environment could recover quickly.

Nutrient availability, temperature, energy supply (i.e., soluble **carbon** for most **microorganisms** or light and **carbon dioxide** for plants), and oxygen status all affect the growth and sustainability of aquatic plants and animals. One condition that perpetuates hypoxia is elevated temperatures because the ability of water to hold oxygen (i.e. water solubility) decreases with increasing temperature. Situations that promote consumption of oxygen such as plant and animal **respiration** and **decomposition** can also lead to hypoxic conditions in water. Therefore, situations that stimulate plant (i.e. phytoplankton, benthic algae and macroalgae) growth in water can lead indirectly to hypoxic conditions. Algal growth can be accelerated with elevated levels of carbon dioxide and certain nutrients (especially nitrogen and phosphorus), provided adequate sunlight is available. Low **sediment** loads also support increased algal growth because the water is less turbid allowing more light to penetrate to the bottom.

In the last two decades of the twentieth century, the increased incidence of hypoxia and the expanded size of dead zones have been the result of increased nutrients coming from human sources. Runoff from residential and agricultural activities are loaded with fertilizers, animal wastes, and sewage that have specific nutrients that can stimulate plant growth. In the United States, nutrient runoff has become a major concern for the entire interior watersheds of the Mississippi River Basin which drains into the Gulf of Mexico.

Hypoxic waters occur near the mouths of many large rivers around the world and in coastal estuaries and enclosed coastal seas. In fact, over 40 hypoxic zones have been identified throughout the world. Robert J. Diaz from the Virginia Institute of Marine Science has studied the global patterns of hypoxia and has concluded that the extent of these zones has increased over the past several decades. Hypoxic zones are occurring in the Baltic Sea, Kattegat, Skagerrak Dutch Wadden Sea, **Chesapeake Bay**, Long Island Sound, and northern Adriatic Sea, as well as the extensive one that occurs at the mouth of the Mississippi River in the Gulf of Mexico.

It is interesting to note that one of the largest hypoxic zones documented occurred in conjunction with the increase in ocean temperatures associated with **El Niño**. This weather event occurs periodically off the west coast of North and South America, and influences not only the winter weather in North America, but also affects the anchovy catch off Peru in the Pacific. This in turn, affects the worldwide price for protein meal and has a direct impact on soybean farmers (since this is another major source of protein for this product).

The large hypoxic zone in the northern Gulf of Mexico occurs where the Mississippi and Atchafalya rivers enter the ocean. The zone was first mapped in 1985, and has doubled in size since then. The Gulf of Mexico dead zone fluctuates in size depending on the amount of river flow entering the Gulf, and on the patterns of coastal winds that mix the oxygen-poor bottom waters of the Gulf with Mississippi River water. The zone in 1999 exceeded 8,006 mi^2 (20,720 km^2) in area, making it one of the largest in the world. This zone fluctuates seasonally, as do others. It can form as early as February and last until October. The most widespread and persistent conditions exist from mid-May to mid-September.

Recent research has shown that increased nitrogen concentrations in the river water, which act like **fertilizer**, stimulate massive phytoplankton blooms in the Gulf. Bacteria decomposing the dead phytoplankton consume nearly all of the available oxygen. This, combined with a seasonal layering of the fresh water from the river and salt water in

the Gulf, results in the zone of low-dissolved oxygen. Within the zone there are very small fish and shellfish populations.

The effect of periodic events on the transport of nutrients to the Gulf, derived primarily from fertilizer in areas of intensive agriculture in the upper Mississippi River Basin, have been implicated as the most likely cause. The largest amount of nutrients is delivered each year after the spring thaw when streams fill and concentrations of nutrients, such as nitrogen, are highest. In addition, during extreme high-flow events, such as those that occurred during the floods of 1993, very high amounts of nutrients are transported to the Gulf. Levels were 100% higher in that year than in other years.

The nature of the hypoxia problem in the Gulf is complicated by the fact that some nutrient load from the Mississippi River is vital to maintain the productivity of the Gulf fisheries but in levels considerably lower than are now entering the marine system. Approximately 40% of the U.S. fisheries landings comes from this area, including a large amount of the shrimp harvest. In addition, the area also supports a valuable sport fishing industry. The concern is that the hypoxic zone has been increasing in size since the 1960s due to human activities in the Mississippi **Watershed** that have increased nitrogen loads to the Mississippi River. The impact of an expanding Gulf hypoxia include: large algal blooms that affect other aquatic organisms, altered ecosystems with changes in plant and fish populations (i.e., lower **biodiversity**), reduced economic productivity in both commercial and recreational fisheries, and both direct and indirect impact on fisheries such as direct **mortality** and altered **migration** patterns which may lead to declines in populations.

Studies were conducted during the 1990s on the sources of increased nutrient concentrations within the Mississippi River. A significant amount of nutrients delivered to the Gulf come from the Upper Mississippi and Ohio River watersheds. The amount of dissolved nitrogen and phosphorus in the waters of the Mississippi has more than doubled since 1960. The principal areas contributing nutrients are streams draining the corn belt states, particularly Iowa, Illinois, Indiana, Ohio, and southern Minnesota. About 60% of the nitrate transported by the Mississippi River comes from a land area that occupies less than 20% of the basin. These watersheds are predominantly agricultural and contain some of the most productive farmland in the world. This area produces approximately 60% of the nation's corn. The U.S. **Geological Survey** has estimated that 56% of the nitrogen entering the Gulf hypoxic zone originates from fertilizer. Potential agricultural sources within these regions include runoff from cropland, animal grazing areas, **animal waste** facilities, and input from agricultural **drainage** systems. The contributions to nutrient input from sources such as **atmospheric deposition**, coastal upwelling, and industrial sources within the lower Mississippi Watershed are being evaluated also. It is unclear what effect the damming and channelization of the river for navigation has on nutrient delivery. The dead zone area in the Gulf will continue to be monitored to determine whether it continues to expand.

In the meantime, efforts to reduce nutrient **loading** are being undertaken in agricultural areas across the watershed. Several strategies to reduce nutrient loading have been drafted. They are: a reduction in nitrogen-based fertilizers and runoff from **feedlots**, planting alternative crops that do not require large amounts of fertilizers, removing nitrogen and phosphorus from **wastewater**, and restoring **wetlands** so that they can act as reservoirs and **filters** for nutrients. Depending on whether the zone continues to expand or decreases as nutrient levels diminish will determine whether it remains a significant environmental problem in the Gulf of Mexico. Knowledge gained from the study of changing nutrient loads in the Mississippi River will be useful in addressing similar problems in other parts of the world.

Debt for nature swap

Debt for **nature** swaps are designed to relieve developing countries of two devastating problems: spiraling debt burdens and **environmental degradation**. In a debt for nature swap, developing country debt held by a private bank is sold at a substantial discount on the secondary debt market to an environmental **nongovernmental organization** (NGO). The NGO cancels the debt if the debtor country agrees to implement a particular environmental protection or **conservation** project. The arrangement benefits all parties involved in the transaction. The debtor country decreases a debt burden that may cripple its ability to make internal investments and generate economic growth. Debt for nature swaps may also be seen as a good alternative to defaulting on loans, which hurts the country's chances of receiving necessary loans in the future. In addition, the country enjoys the benefits of curbing environmental degradation. The creditor (bank) decreases its holdings of potentially bad debt, which

may have to be written off at a loss. The NGO experiences global environmental improvement.

Debt for nature swaps were first suggested by Thomas Lovejoy in 1984. Swaps have taken place between Bolivia, Costa Rica, and Ecuador and NGOs in the United States. The first debt for nature swap was implemented in Bolivia in 1987. **Conservation International**, an American NGO, purchased $650,000 of Bolivia's foreign debt from a private bank in the United States at a discounted price of $100,000. The NGO then swapped the face value of the debt with the Bolivian government for "conservation payments-in-kind," which involved a conservation program in a 3.7 million acre (1.5 million ha) tropical forest region implemented by the government and a local NGO.

Despite the benefits associated with debt for nature swaps, implementation has been minimal so far. Less than two percent of the $38 billion in debt for equity swaps have been debt for nature swaps. A lack of incentives on the part of the debtor or the creditor and the lack of well-developed supporting institutional infrastructure can hinder progress in arranging debt for nature swaps.

If a debtor country is unable to repay foreign debt, it has the option of defaulting on the loans or agreeing to a debt for nature swap. The country has an incentive to agree to a debt for nature swap if defaulting is not a viable option and if the benefits of decreasing debt through a swap outweigh the costs of implementing a particular environmental protection project. The cost of the environmental protection programs can be substantial if the developing country does not have the appropriate institutional infrastructure in place. The program will require the input of professional public administrators and environmental experts. Without institutions to support these individuals, the developing countries may find it impossible to carry out the programs they promise to undertake in exchange for cancellation of the debt. If, in addition, the debtor country is highly capital-constrained, then it might not give high priority to the benefits of an environmental investment.

Whether the creditor has an incentive to sell a debt on the secondary debt market to an NGO depends on the creditor's estimate of the likelihood of receiving payment from the developing country; on the proportion of potentially bad credit the creditor is holding; and on its own financial situation. If the NGOs are willing to pay the price demanded by private banks for developing country debt and swap it for environmental protection projects in the debtor countries, they will have the incentive to pursue debt for nature swaps.

Benefits that may be taken into account by the NGOs are those commonly associated with environmental protection. Many developing countries hold the world's richest tropical rain forests, and the global community will benefit greatly from the preservation of these forests. Tropical forests hold a great deal of **carbon dioxide**, which is released into the **atmosphere** and contributes to the **greenhouse effect** when the forests are destroyed. Another benefit is known as "option value," the value of retaining the option of future use of plant or animal resources that might otherwise become extinct. Although we may not know at present of what use, if any, these **species** might be, there is a value associated with preserving them for unknown future use. Examples of future uses might be pharmaceutical remedies, scientific understanding or **ecotourism**. In addition, NGOs may attach "existence value" to environmental amenities. Existence value refers to the value placed on just knowing that natural environments exist and are being preserved. Many NGOs believe preservation is important so that **future generations** can enjoy the **environment**. This value is known as "bequest value." Finally, the NGO may be interested in decreasing hunger and poverty in developing countries, and both the reduction of external debt and the slowing of the depletion of **natural resources** in developing countries is perceived as a benefit for this purpose.

To make a swap attractive, however, the NGO must be assured that the environmental project will be carried out after the debt has been canceled. Without adequate enforcement and assistance, a country might promise to implement an environmental project without being able or willing to follow through. Again, the solution to this problem lies in the development of institutions that are committed to monitoring and giving assistance in the implementation of the programs. Such institutions might encourage long-term relationships between the debtor and NGO to facilitate a structure by which debt is canceled piecemeal on the condition that the debtor continues to comply with the agreement.

A complicating factor that may affect an NGO's **cost-benefit analysis** of debt for nature swaps in the future is that, as the number of swaps and environmental protection projects increases, the value to be derived from any additional projects will decrease, due to diminishing marginal returns.

As described above, the benefits associated with debt for nature swaps both for the debtor countries and NGOs hinge on the presence of supporting institutions in the developing countries. It is particularly important to promote the establishment of appropriate, professionally managed public agencies with adequate resources to hire and maintain environmental experts and managers. These institutions should be responsible for planning and implementing the programs.

It should be noted that, although large debt burdens and environmental degradation are both serious problems faced by many developing countries, there is no direct linkage between them. Nevertheless, debt for nature swaps are an intriguing remedy that seems to address both problems simultaneously. As the quantity and magnitude of swaps so far have been relatively small, it is impossible to say how

successful a remedy it may be on a larger scale. It is clear, though, that the future of debt for nature swaps depends on the development of appropriate incentives to all parties in the swap and on the development of institutions to support the fulfillment of the agreements.

Deciduous forest

Deciduous forests are made of trees that lose their leaves seasonally and are leafless for part of each year. The tropical deciduous forest is green during the rainy season and bare during the annual **drought**. The temperate deciduous forest is green during the wet, warm summers and leafless during the cold winters with the leaves turning yellow and red before falling. Temperate deciduous forests once covered large portions of Europe, eastern United States, Japan, and eastern China. **Species** diversity is highest in Asia and lowest in Europe. In the United States deciduous forest, 67 species of trees exist.

Decline spiral

A decline spiral is the destruction of a **species**, **ecosystem**, or **biosphere** in a continuing downward trend, leading to ecosystem disruption and impoverishment. The term is sometimes used to describe the loss of **biodiversity**, when a catastrophic event has led to a sharp decline in the number of organisms in a **biological community**.

In areas where the **habitat** is highly fragmented either due to human intervention or natural disaster, the loss of species is markedly accelerated. Loss of species diversity often initiates a downward spiral, as the weakening of even one plant or animal in an ecosystem, especially a **keystone species**, can lead to the malfunctioning of the biological community as a whole.

Biodiversity exists at several levels within the same community; it can include ecosystem diversity, species diversity, and genetic diversity. Ecosystem diversity refers to the different types of landscapes that are home to living organisms. Species diversity refers to the different types of species in an ecosystem. Genetic diversity refers to the range of characteristics in the DNA of the plants and animals of a species. A catastrophic event that affects any aspect of the diversity in an ecosystem can start a decline spiral.

Any major catastrophe that results in a decline in biospheric quality and diversity, known as an ecocatastrophe, may initiate a decline spiral. **Herbicide** and **pesticide** used in agriculture, as well as other forms of **pollution**; increased use of **nuclear power**, and exponential **population growth** are all possible contributing factors. The Lapp reindeer herds were decimated by fallout from the nuclear accident at Chernobyl in 1986. Similarly, the oil spill from the *Exxon Valdez* **in 1989 led to a decline spiral to the Gulf of Alaska ecosystem.**

The force that begins a decline spiral can also be indirect, as when **acid rain**, **air pollution**, **water pollution**, or **climate** change kill off many plants or animals in an ecosystem. Diversity can also be threatened by the introduction of non-native or **exotic species**, especially when these species have no natural predators and are more aggressive than the native species. In these circumstances, native species can enter into a decline spiral that will impact other native species in the ecosystem.

Restoration ecology is a relatively new discipline that attempts to recreate or revive lost or severely damaged ecosystems. It is a hands-on approach by scientists and amateurs alike designed to reverse the damaging trends that can lead toward decline spirals. Habitat rebuilding for **endangered species** is an example of restoration **ecology**. For example, the Illinois chapter of **The Nature Conservancy** has reconstructed an oak-and-grassland **savanna** in Northbrook, Illinois, and a **prairie** in the 100-acre (40-ha) ring formed by the underground Fermi National Accelerator Laboratory at Batavia, Illinois. Since it is easier to reintroduce **flora** than the **fauna** into an ecosystem, practitioners of restoration ecology concentrate on plants first. When the plant mix is right, insects, birds, and small animals return on their own to the ecosystem.

Decomposers

Decomposers (also called saprophages, meaning "corpse eating") are the organisms which perform the critical task of **decomposition** in **nature**. They include bacteria, **fungi**, and **detritivores** that break down dead organic matter, re-

leasing nutrients back into the **ecosystem**. Fungi are the dominant decomposers of plant material, and bacteria primarily break down animal matter. Decomposers secrete enzymes into plant and animal material to break down the organic compounds, starting with compounds such as sugars which are easily broken down, and ending with more resistant compounds such as cellulose and lignin. Rates of decomposition are faster at higher values of moisture and temperature. Decomposers thus perform a unique and important function in the **recycling** process in nature.

Decomposition

The chemical and biochemical breakdown of a complex substance into its constituent compounds and elements, releasing energy, and often with the formation of new, simpler substances. Organic decomposition takes place mostly in or on the **soil** under **aerobic** conditions. Dead plant and animal materials are consumed by a myriad of organisms, from mice and moles, to worms and beetles, to **fungi** and bacteria. Enzymes produced by these organisms attack the decaying material, releasing water, **carbon dioxide**, nutrients, **humus**, and heat. New microbial cells are created in the process.

Decomposition is a major process in **nutrient** cycling, including the **carbon** and **nitrogen** cycles. The liberated carbon dioxide can be absorbed by photosynthetic organisms, including green plants, and made into new tissue in the **photosynthesis** process, or it can be used as a carbon source by autotrophic organisms.

Decomposition also acts on inorganic substances in a process called **weathering**. Minerals broken free from rocks by physical disintegration can chemically decompose by reacting with water and other **chemicals** to release elements, including potassium, calcium, magnesium, and iron. These and other elements can be taken up by plants and **microorganisms**, or they can remain in the soil system to react with other constituents, forming clays.

Deep ecology

The term "deep ecology' was coined by the Norwegian environmental philosopher Arne Naess in 1973. Naess drew a distinction between "shallow" and "deep" **ecology**. The former perspective stresses the desirability of conserving **natural resources**, reducing levels of air and **water pollution**, and other policies primarily for promoting the health and welfare of human beings. Deep ecologists maintain that shallow ecology simply accepts, uncritically and without reflection, the homocentric, or human-centered, view that humans are, or ought to be, if not the masters of **nature**, then at least the managers of nature for human ends or purposes. Defenders of deep ecology, by contrast, claim that shallow **environmentalism** is defective in placing human interests above those of animals and ecosystems. Human beings, like all lower creatures, exist within complex webs of interaction and interdependency. If people insist on conquering, dominating, or merely managing nature for their own benefit or amusement, if people fail to recognize and appreciate the complex webs that hold and sustain them, they will degrade and eventually destroy the natural **environment** that sustains all life.

But, deep ecologists say, if people are to protect the environment for all **species**, now and in the future, they must challenge and change long-held basic beliefs and attitudes about our species place in nature. For example, people must recognize that animals, plants, and the ecosystems that sustain them have intrinsic value—that is, are valuable in and of themselves—quite apart from any use or instrumental value they might have for human beings. The genetic diversity found in insects and plants in tropical rain forests is to be protected not (only or merely) because it might one day yield a drug for curing **cancer**, but also and more importantly because such **biodiversity** is valuable in its own right. Likewise, rivers and lakes should contain clean water not just because humans need uncontaminated water for swimming and drinking, but also because fish do. Like Gandhi, to whom they often refer, deep ecologists teach respect for all forms of life and the conditions that sustain them.

Critics complain that deep ecologists do not sufficiently respect human life and the conditions that promote prosperity and other human interests. Some go so far as to claim that they believe in the moral equivalence of human and all other life-forms. Thus, say the critics, deep ecologists would assign equal value to the life of a disease-bearing mosquito and the child it is about to bite. No human has the right to swat or spray an insect, to kill pests or predators, and so on. But in fact this is a caricature of the stance taken by deep ecology. All creatures, including humans, have the right to protect themselves from harm, even if that means depriving a mosquito of a meal or even eliminating it altogether. **Competition** within and among species is normal, natural, and inevitable. **Bats** eat mosquitoes; bigger fish eat smaller fish; humans eat big fish; and so on. But for one species to dominate or destroy all others is neither natural nor sustainable. Yet human beings have, through technology, an ever-increasing power to destroy entire ecosystems and the life that they sustain. Deep ecologists hold that this power has corrupted human beings and has led them to think—quite mistakenly—that human purposes are paramount and that human interests take precedence over those of lower or lesser species. Human beings cannot exist independently from, but only interdependently with nature's myriad species. Once people recognize the depth and degree

of this interdependence, deep ecologists say, they will learn humility and respect. The human species' proper place is not on top, but within nature and with nature's creatures and the conditions that nurture all.

Some cultures and religions have long taught these lessons. Zen Buddhism, Native American religions, and other nature-centered belief systems of belief have counseled humility toward, and respect for, nature and nonhuman creatures. But the dominant Western reaction is to dismiss these teachings as primitive or mystical. Deep ecologists, by contrast, contend that considerable wisdom is to be found in these native and non-Western perspectives.

Deep ecology is at present a philosophical perspective within the environmental movement, and not a movement in itself. This perspective does, however, inform and influence the actions of some radical environmentalists. Organizations such as **Earth First!** and the **Sea Shepherd Conservation Society** are highly critical of moderate shallow environmental groups which are prepared to compromise with loggers, developers, dam builders, strip miners, and oil companies, thus putting the economic interests of some human beings ahead of all others. Such development destroys **habitat**, endangers entire species of animals and plants, and proceeds on the assumption that nature has no **intrinsic value**, but only instrumental value for human beings. It is this assumption, and the actions that proceed from it, that deep ecology is questioning and attempting to change. *See also* Ecosophy; Environmental ethics; Foreman, Dave; Green politics; Greens; Strip mining

Deep-well injection

Injection of liquid wastes into subsurface geologic formations is a technology that has been widely adopted as a waste-disposal practice. The practice entails drilling a well to a **permeable**, saline-bearing geologic formation that is confined above and below with impermeable layers known as confining beds. When the injection zones lie below drinking water sources at depths typically between 2,000–5,000 ft (610–1,525 m), they are referred to as Class I disposal **wells**. The liquid **hazardous waste** is injected at a pressure that is sufficient to replace the native fluid and yet not so high that the integrity of the well and confining beds is at risk. Injection pressure is a limiting factor because excessive pressure can cause hydraulic fracturing of the injection zone and confining strata, and the intake rate of most injection wells is less than 400 gal (1,500 l) per minute.

Deep-well injection of liquid waste is one of the least expensive methods of **waste management** because little waste treatment occurs prior to injection. Suspended solids must be removed from **wastewater** prior to injection to prevent them from plugging the pores and reducing permeability of the injection zone. Physical and chemical characteristics of the wastewater must be considered in evaluating its suitability for disposal by injection.

The principal means of monitoring the wastewater injection process is recording the flow rate, the injection and annulus pressures, and the physical and chemical characteristics of the waste. Many consider this inadequate and monitoring is still a controversial subject. The major question which arises concerns the placement of monitoring wells and whether they increase the risk that wastewater will migrate out of the injection zone if they are improperly constructed.

Deep-well injection of wastes began as early as the 1950s, and it was then accepted as a means of alleviating surface **water pollution**. Today, most injection wells are located along the Gulf Coast and near the **Great Lakes**, and their biggest users are the **petrochemical**, pharmaceutical, and steel mill industries.

As with all injection wells, there is a concern that the waste will migrate from the injection zone to the overlying aquifers. *See also* Aquifer restoration; Groundwater monitoring; Groundwater pollution; Hazardous waste siting; Hazardous waste site remediation; Water quality

Defenders of Wildlife

Defenders of Wildlife was founded in 1947 in Washington, D.C. Superseding older groups such as Defenders of Furbearers and the Anti-Steel-Trap League, the organization was established to protect wild animals and the habitats that support them. Today their goals include the preservation of **biodiversity** and the defense of **species** as diverse as gray **wolves** (*Canis lupus*), **Florida panthers** (*Felis concolor coryi*), and grizzly bears (*Ursus arctos*), as well as the western yellow-billed cuckoo (*Coccyzus americanus*), the **desert tortoise** (*Gopherus agassizii*), and Kemp's Ridley sea turtle (*Lepidochelys kempii*).

Defenders of Wildlife employs a wide variety of methods to accomplish their goals, from research and education to lobbying and litigation. They have achieved a ban on livestock grazing on 10,000 acres (4,050 ha) of tortoise **habitat** in Nevada and lobbied for restrictions on the international wildlife trade to protect **endangered species** in other countries. In 1988 they successfully lobbied Congress for funding to expand wildlife refuges throughout the country. Ten million dollars was appropriated for the Lower Rio Grande **National Wildlife Refuge** in Texas, two million dollars to purchase land for a new preserve along the Sacramento River in California, and $1 million for additions to the Rachel Carson National **Wildlife Refuge** in Maine. They are currently seeking passage of the National Biological Diversity Conservation and Research Act and the American Heritage Trust Fund, which would support the continued acquisition of natural habitats.

The organization has been at the forefront of placing preservation on an economic foundation. In Oregon, they have overseen the establishment of a number of areas from which to view wildlife on public and private land, thus improving access to natural habitats and linking the **environment** with the economic benefits of the state's tourism industry. Defenders maintains a speaker's bureau, and they support a number of educational programs for children designed to nourish and expand their interest in wildlife. But the group also participates in more direct action on behalf of the environment. They coordinate grassroots campaigns through their Defenders Activist Network, which has a membership of 9,000. They work with the **Environmental Protection Agency** on a hotline called the "Poison Patrol," which receives calls on the use of pesticides that damages wildlife, and they belong to the *Entanglement Network Coalition*, which works to prevent the loss of animal life through entanglement in nets and plastic refuse.

Restoring wolves to their natural habitats has long been one of the top priorities of Defenders of Wildlife. In 1985, they sponsored an exhibit in **Yellowstone National Park** and at Boise, Idaho, called "Wolves and Humans," which received over 250,000 visitors and won the **Natural Resources** Council of America Award of Achievement for Education. They have helped reintroduce red and gray wolves back into the northern Rockies. In order to assist farmers and the owners of livestock herds that graze in these areas, Defenders has raised funds to compensate them for the loss of land. They are also working to reduce and eventually eliminate the **poisoning** of predators, both by lobbying for stricter legislation and by encouraging Western farmers to participate in their guard dog program for livestock.

In order to conserve land, the Defenders have also launched their own coffee line called "Java Forest." The coffee beans are grown under the forest canopy or on farms which recreate a natural habitat. This reduces the large amount of land that is used for hybrid coffee beans. Twenty-five percent of each purchase is being returned to the Defenders to be used in other programs.

Defenders of Wildlife has 425,000 members and an annual budget of $5.2 million. In addition to wildlife viewing guides for different states, their publications include a bimonthly magazine for members called *Defenders* and *In Defense of Wildlife: Preserving Communities and Corridors.*.

Defoliation

Several factors can cause a plant to lose its leaves and become defoliated. Defoliation is a natural and regular occurrence in the case of deciduous trees and shrubs that drop their leaves each year with the approach of winter. This process is aided by an abscission layer that develops at the base of the leaf petiole, weakens the attachment to the plant, and eventually causes the leaf to drop. Severe **drought** may also cause leaves to wilt, dry and drop from a plant. The result of severe dehydration is usually lethal for herbaceous plants, although some woody **species** may survive an episode of drying. Heavy infestation by leaf-eating insects can lead to partial, or complete defoliation. The **gypsy moth** (*Porthetria dispar*) is an important defoliator that attacks many trees, defoliating, and weakening, or killing them. Parasitic wasps that feed on the larvae can help to control gypsy moth outbreaks. Insecticide sprays have also be used to kill the larvae. Spider mites, any of the plant-feeding mites of the family Tetranychidae (subclass Acari), feed on house plants and the foliage and fruit of orchard trees. Heavy infestation can lead to serious or complete defoliation. Spider mites are

controlled with pesticides, although growing **resistance** to chemical control agents has made this more difficult, and alternative control measures are under investigation.

Along with natural causes of defoliation, **chemicals** can cause plants to drop their leaves. The best known and most widely used chemical defoliators are 2,4,5 trichlorophenoxyacetic **acid** (**2,4,5-T**) and 2,4 dichlorophenoxyacetic acid (**2,4-D**). Both chemicals are especially toxic to broadleaf plants. The **herbicide** 2,4-D is widely used in lawn care products to rid lawns of dandelions, clover, and other broadleaf plants that interfere with robust turf development. At appropriate application rates, it selectively kills broad-leaf herbaceous plants, and has little effect on narrow-leaf grasses. The uses of 2,4,5-T are similar, although it has been more widely used against woody species.

A mixture of 2,4-D and 2,4,5-T, in a product called **Agent Orange** has been extensively used to control the growth and spread of woody trees and shrubs in sites earmarked for industrial or commercial development. Agent Orange saw extensive use by American forces in Southeast Asia during the Vietnam war, where it was used initially to clear for power lines, roads, railroads, and other lines of communication. Eventually, as the war continued, it was used to spray enemy hiding places, and U.S. military base perimeters to prevent surprise attack. Food crops, especially rice, were also targets for Agent Orange to deprive enemy forces of food. Although Agent Orange and other formulations containing the chlorinated phenoxy acetic acid derivatives are generally lethal to herbaceous plants, woody deciduous plants may survive one or more treatments, depending on the species treated, concentrations used, spacing of applications, and weather. In Vietnam it was found that mangrove forests in the Mekong delta were especially sensitive, and often killed by a single treatment. A member of the **dioxin** family of chemicals, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) has been found to be an accidental but common contaminant of 2,4,5-T and Agent Orange. Dioxins are very resistant to attack by **microbes** in the **environment**, and are apt to persist in soils for a very long time. Although few disorders have been definitively proven to be caused by dioxins, their effects on laboratory animals have caused some scientists to rank them among the most poisonous substances known. The U.S. government banned some 2,4,5-T containing products in 1979 because of uncertainties regarding its safety, but its use continues in other products.

Deforestation

Deforestation is the complete removal of a forest **ecosystem** and conversion of the land to another type of landscape. It differs from **clear-cutting**, which entails complete removal of all standing trees but leaves the **soil** in a condition to regrow a new forest if seeds are available. Humans destroy forests for many reasons. American Indians burned forests to convert them to **grasslands** that supported big game animals. Early settlers cut and burned forest to convert them to croplands. Between 1600 to 1909, European settlement decreased forest cover in the United States by 30%. Since that time, total forest acreage in the United States has actually increased. In Germany about two-thirds of the forest was lost through settlement. Food and Agriculture Organization (FAO) estimated that from 1980 to 1990, 0.9% of remaining tropical forests were deforested annually (65,251 mi^2 [169,000 km^2] per year), an area equivalent to the state of Washington. FAO defines forest as land with more than 10% tree cover, natural understory vegetation, **nature** animals, natural soils, and no agriculture. Analysis of deforestation is difficult because data is unreliable and the definitions for "forest" and "deforestation" keep changing; for example, clear-cuttings which reforest within five years have been considered deforested in some studies but not in others.

The major direct causes of topical deforestation are the expansion of shifting agriculture, livestock production, and fuelwood harvest in drier regions. Forest conversion to permanent cropland, infrastructure, urban areas, and commercial fisheries also occurs. Although not necessarily resulting in deforestation, timber harvest, grazing, and fires can severely degrade the forest. The environmental costs of deforestation can include **species extinction**, **erosion**, **flooding**, reduced land productivity, **desertification**, and **climate** change and increased atmospheric **carbon dioxide**. As more **habitat** is destroyed, more species are facing extinctions. Deforestation of watersheds causes erosion, flooding, and **siltation**. Upstream land loses fertile **topsoil** and downstream crops are flooded, hydroelectric reservoirs are filled with **silt** and fisheries are destroyed. In drier areas, deforestation contributes to desertification.

Deforestation can alter local and regional climates because evaporation of water from leaves makes up as much as two-thirds of the rain that falls in some forest. Without trees to hold back surface **runoff** and block wind, available moisture is quickly drained away and winds dry the soil,

sometimes resulting in desert-like conditions. Another potential effect on climate is the large scale release into the **atmosphere** of **carbon** dioxide stored as organic carbon in forests and forest soils. In 1980, tropical deforestation released between 0.4 and 1.6 billion tons of carbon into the atmosphere, an amount equal to 10–40% of that from **fossil fuels**.

As a result of misguided deforestation in the moist and dry tropics, the rural poor are deprived of construction materials, fuel, food, and cash crops harvested from the forest. Species extinctions, siltation, and flooding expand these problems to national and international levels. Despite these human and environmental costs, wasteful deforestation continues. Current actions to halt and reverse deforestation focus on creating economic and social incentives to reduce wasteful land conversion by providing for wiser ways to satisfy human needs. Other efforts are the reforestation of deforested areas and the establishment and maintenance of **biodiversity** preserves.

Delaney Clause

The Delaney Clause is a part of the Federal Food, Drug, and Cosmetic Act of 1958, Section 409, and it prohibits the addition to food of any substance that will cause **cancer** in animals or humans. The clause states "no additive will be deemed to be safe if it is found to induce cancer when ingested by man or animal, or if it is found, after tests which are appropriate for the evaluation of the safety of **food additives**, to induce cancer in man or animals..." The clause addresses the safety of food intended for human consumption and few, if any, reasonable individuals would argue with its intent.

There is however, an emerging scientific controversy over its application, and many now question the merits of the clause as it is written. For example, safrole occurs naturally as a constituent in sassafras tea and spices and thus permissibly under the Delaney Clause, but it is illegal and banned as an additive to natural root beer because it has been proven a **carcinogen** in animal tests. Coffee is regularly consumed by many individuals, yet more than 70% of the tested **chemicals** that occur naturally in coffee have been shown to be carcinogenic in one or more tests. Naturally occurring carcinogens are found in other foods including lettuce, apples, pears, orange juice, and peanut butter. It is important to note here that the National Cancer Institute recommends the consumption of fruits and vegetables as part of a regimen to reduce cancer risk. This is because it is widely believed that the positive effects of fruits and vegetables far outweigh the potential hazard of trace quantities of naturally occurring carcinogens.

It has been estimated that about 10,000 natural pesticides of plants are consumed in the human diet. These natural pesticides protect the plants from disease and predation by other organisms. Only a few of these natural plant pesticides (less than 60) have been adequately tested for carcinogenic potential and of these about half of them tested positive. Bruce N. Ames and his associates at the University of California estimate that 99.99% of the pesticides ingested by humans are not residues of chemicals applied by humans but are chemicals that occur naturally and therefore legally. It has been argued that such naturally occurring chemicals are less hazardous and thus differ in their cancer-causing potential from synthetic chemicals. But this does not appear to be the case; although the mechanisms for chemical carcinogenesis are poorly understood, there seems to be no fundamental difference in how natural and synthetic carcinogens are metabolized in the body.

The Delaney Clause addresses only the issue of additives to the food supply. It is noteworthy that salt, sugar, corn syrup, citric **acid** and baking soda comprise 98% of the additives listed, while chemical additives, which many fear, constitute only a small fraction. It should also be noted that there are other significant safety issues pertaining to the food supply, including pathogens which cause botulism, hepatitis, and salmonella food **poisoning**. Of similar concern to health are traces of environmental pollutants, such as **mercury** in fish, and cooking-induced production of carcinogens, such as **benzopyrene** in beef cooked over an open flame. Excess fat in the diet is also thought to be a significant health hazard.

Scientists who are rethinking the significance of the "zero risk" requirement of the Delaney Clause do not believe society should be unconcerned about chemicals added to food. They simply believe the clause is no longer consistent with current scientific knowledge, and they argue that chemicals added in trace quantities, for worthwhile reasons, should be considered from a different perspective. *See also* Agricultural chemicals; Agricultural pollution; Drinking-water supply; Food and Drug Administration

Demographic transition

Developed by demographer Frank Notestein in 1945, this concept describes the typical pattern of falling death and birth rates in response to better living conditions associated with economic development. This idea is important, for it offers the hope that developing countries will follow the same pathway to population **stability** as have industrialized countries. In response to the Industrial Revolution, for example, Europe experienced a population explosion during the nineteenth century. Emigration helped alleviate overpopulation, but European couples clearly decided on their own to limit family size.

Notestein identified three phases of demographic transition: preindustrial, developing, and modern industrialized societies. Many authors add a fourth phase, postindustrial. In phase one, birth rates and death rates are both high with stable populations. As development provides a better food supply and **sanitation**, death rates begin to plummet, marking the onset of phase two. However, birth rates remain high, as families follow the pattern of preceding generations. The gap between high birth rates and falling death rates produces a population explosion, sometimes doubling in less than 25 years.

After one or two generations of large, surviving families, birth rates begin to taper off, and as the population ages, death rates rise. Finally a new balance is established, phase three, with low birth and death rates. The population is now much larger yet stable. The experience of some European countries, especially in Central Europe and Russia, suggests a fourth phase where populations actually decline. This may be a response to past hardships and oppressive political systems there, however.

Historically, birth rates have always been high. With few exceptions population explosions are linked to declining death rates, not rising birth rates. Infants and young children are especially vulnerable; sanitation and proper food are vital. Infant survival is seen by some as a threat because of the built-in momentum for **population growth**. However, history reveals that there has been no decline in birth rates which has not been preceded by a drop in infant **mortality**. In a burgeoning world this makes infant survival a matter of top priority. To this end, in 1986 the United Nations adopted a program with the acronym GOBI: Growth monitoring, Oral rehydration therapy (to combat killer diarrhea), Breast feeding, and Immunization against major **communicable diseases**. *See also* Child survival revolution; Population Council

Denitrification

A stage in the **nitrogen cycle** in which **nitrates** in the **soil** or in dead organic matter are converted into nitrite, **nitrous oxide**, ammonia, or (primarily) elemental **nitrogen**. The process is made possible by certain types of bacteria, known as denitrifying bacteria. Denitrification is a reduction reaction and occurs, therefore, in the absence of oxygen. For example, flooded soil is likely to experience significant denitrification since it is cut off from atmospheric oxygen. Although denitrification is an important process for the decay of dead organisms, it can also be responsible for the loss of natural and synthetic fertilizers from the soil.

Deoxyribose nucleic acid

Deoxyribose **nucleic acid** (DNA) molecules contain genetic information that is the blueprint for life. DNA is made up of long chains of subunits called nucleotides, which are nitrogenous bases attached to ribose sugar molecules. Two of these chains intertwine in the famous double helix structure discovered in 1953 by James Watson and Francis Crick.

The genetic information contained in DNA molecules is in a code spelled out by the linear sequence of nucleotides in each chain. Each group of three nucleotides makes up a codon, a unit resembling a letter in the alphabet. A string of codons effectively spells a word of the genetic message.

This message is expressed when enzymes (cellular proteins) synthesize new proteins using a copy of a short segment of DNA as a template. Each nucleotide codon specifies which amino **acid** subunit is inserted as the protein is formed, thus determining the structure and function of the

proteins. Because the chains are very long, a single DNA strand can contain enough information to direct the synthesis of hundreds of different proteins. Since these proteins make up the cell structure and the machinery (enzymes) by which cells carry out the processes of life, such as synthesizing more molecules including more copies of the DNA itself, DNA can be said to be self-replicating. When cells divide, each of the new cells receives a duplicate set of DNA molecules giving them the necessary information to live and reproduce. *See also* Ribosenucleic acid

Desalinization

Desalinization, also known as "desalination," is the process of separating sea water or **brackish** water from their dissolved salts. The average salt content of the ocean water is about 3.4% (normally expressed as 34 parts per thousand). The range of salt content varies from 18 parts per thousand in the North Sea and near the mouths of large rivers to a high of 44 parts per thousand in locked bodies of water such as the Red Sea, where evaporation is very high. The desalination process is accomplished commercially by either distillation or reverse osmosis (RO).

Distillation of sea water is accomplished by boiling water and condensing the vapor. The components of the distillation system consist of a boiler and a condenser with a source of cooling water. Reverse osmosis is accomplished by forcing filtered sea water or brackish water through a reverse osmosis membrane. In a reverse osmosis process, approximately 45% of the pressurized sea water goes through membranes and becomes fresh water. The remaining brine (concentrated salt water) is returned to the sea.

In 1980, the United Nations declared 1981–1990 as the "International Drinking Water Supply and **Sanitation** Decade." The objective was to provide safe drinking water and sanitation to developing nations. Despite some progress in India, Indonesia, and a few other countries, the percentage of the world population with access to safe drinking water has not changed much since that declaration. In the period between 1990 and 2000, the amount of people with access has only increased by 5%.

The World Health Organization (WHO) estimates that only two in five people in the **less developed countries** (LDCs) have access to safe drinking water. The WHO also estimates that at least 25 million people of the LDCs die each year because of polluted water and from water-born diseases such as **cholera**, polio, dysentery, and typhoid. Whether by distillation or by reverse osmosis, desalination of water can transform water that is unusable because of its **salinity** into valuable fresh water. This could be an important water source in many drought-prone areas.

Desalination plants, distribution, and functions

There are approximately 7,500 desalination plants worldwide. Collectively they produce less than 0.1% of the world's fresh water supply. This supply is equal to about 3.5 billion gal per day (13 million l). The cost and the feasibility of producing desalinated water depends upon the cost of energy, labor, and relative costs of desalinated water to that of imported fresh water. It is estimated that in the United States, commercial desalinated water produced from sea water by reverse osmosis costs about $3 per 1,000 gal (3,785 l). This price is four to five times the average price currently paid by urban consumers for drinking water and over 100 times the price paid by farmers for **irrigation** water. The current energy requirement is approximately three kilowatt hours of electricity per one gallon of fresh water extracted from sea water. Currently, using desalinated water for agriculture is cost prohibitive.

About two-thirds of the desalination water is produced in Saudi Arabia, Kuwait, and North Africa. Several small-scale reverse osmosis plants are now operating in the United States, including California (Santa Barbara, Catalina Island, and soon in Ventura and other coastal communities). Generally, desalination plants are used to supplement the existing fresh water supply in areas adjacent to oceans and seas such as southern California, the Persian Gulf region, and other dry coastal areas. Among the advantages of desalinized water are a dependable water supply regardless of rainfall patterns, elimination of **water rights** disputes, and the preservation of the fresh water supply, all of which are essential for existing natural ecosystems.

Reverse osmosis

Reverse osmosis involves forcing water under pressure through a **filtration** membrane that has pores small enough

to allow water molecules to pass through but exclude slightly larger dissolved salt molecules. The basic parts of a reverse osmosis system include onshore and offshore components. The onshore components consist of a water pump, an electrical power source, pre-treatment filtration (to remove seaweed and debris), reverse osmosis units connected in series, **solid waste** disposal equipment, and fresh water pumps. The offshore components consist of an underwater intake pipeline, approximately 1,093 yd (1 km) from shore, and a second pipeline for brine **discharge**.

Small reverse osmosis units for home use with a few gallons-per-day capacity are available. These units use a disposable reverse osmosis membrane. Their main drawback is that they waste four to five times the volume of water they purify.

Producing potable water from sea water is an energy intensive, costly process. The high cost of producing desalinized water limits its use to domestic consumption. In areas such as the Persian Gulf and Saudi Arabia where energy is plentiful at a low cost, desalinized water is a viable option for drinking water and very limited greenhouse agriculture. The notion of using desalinized water for wider agricultural purposes is neither practical nor economical at today's energy prices and available technology.

Desert

Six percent of the world's land surface is desert, a **biome** in which less than 10 in (25 cm) of precipitation occurs per year or any place where evaporation greatly exceeds precipitation, resulting in a lack of available moisture. Sometimes any area lacking the necessary conditions to support life is called a desert. Deserts occur around latitudes 30 degrees north and south where masses of dry circulating air descend to the earth's surface. There are three kinds of deserts—hot (such as Sahara), temperate (such as the Mojave), and cold (such as the Gobi). The area of global desert is increasing yearly, as marginal lands become degraded by human misuse resulting in **desertification**. Deserts are potential sites for the production of electricity using banks of solar cells or parabolic solar collectors. The lack of water and remoteness of some deserts may make them attractive places to store nuclear and other hazardous wastes.

Desert tortoise

The **desert** tortoise (*Gopherus agassizii*) is a large, herbivorous, terrestrial turtle of the family Testudinidae. It is found in both the southwestern United States and in northwestern Mexico. It is the official reptile in the states of California and Nevada. No other turtle in North America shares the extreme conditions of the habitats occupied by the desert tortoise. It inhabits desert oases, washes, rocky hillsides, and canyon bottoms with sandy or gravelly **soil** under hot, **arid** conditions.

Desert tortoises dig into dry, gravelly soil under bushes in arroyo banks or at the base of cliffs to construct a burrow, which is their home. Climatic conditions dictate daily activity patterns of these tortoises, and they can relieve the problems of high body temperature and evaporative water loss by retreating into their burrows. Since many desert tortoises live in areas devoid of water, except for infrequent rains, they must rely on their food for their water.

The active period for the desert tortoise is from March through September, after which they enter a hibernation period. Nesting and egg laying activities extend from May through July. Desert tortoises lay an average of five moisture-proof eggs, an **adaptation** that helps retain water in its harsh **environment**. These tortoises reach sexual maturity at 15–20 years, and they have a life span of up to 80 years.

The desert tortoise is very sensitive to human disturbances, and this has led to the decimation of many of its populations throughout the desert southwest. The Beaver Dam Slope population of southwestern Utah has been studied over several decades and shows some of the general tendencies of the overall population. In the 1930s and 1940s the desert tortoise population in this area exhibited densities of about 160 adults per square mile. By the 1970s this density had fallen to less than 130 adults per square mile, and more recent studies indicate the level is now about 60 adults per square mile. In southeastern California at least one population reaches densities of 200 adults per square mile, but overall tendencies show that populations are drastically declining. Recent estimates indicate that there are about 100,000 individual desert tortoises existing in the Mojave and Sonoran deserts.

Desert tortoise populations are listed as threatened in Arizona, California, Nevada, and Utah. Numerous factors are contributing to its decline and vulnerability. **Habitat** loss through human encroachment and development, overcol-

A desert tortoise in the Desert Tortoise Natural Area, Mojave Desert, California. (Photograph by Dan Suzio. Reproduced by permission.)

lecting for the **pet trade**, and vandalism—including shooting tortoises for target practice and flipping them over onto their backs, causing them to die from exposure—have decimated populations. Other factors contributing to their decline are grazing livestock, which trample them or their burrows, and mining operations, which also causes respiratory infections among the desert tortoises. Numerous desert tortoises have been killed or maimed by **off-road vehicles**, which also collapse the tortoises' burrows. Concern is mounting as **conservation** efforts seem to be having little effect throughout much of the desert tortoise's range.

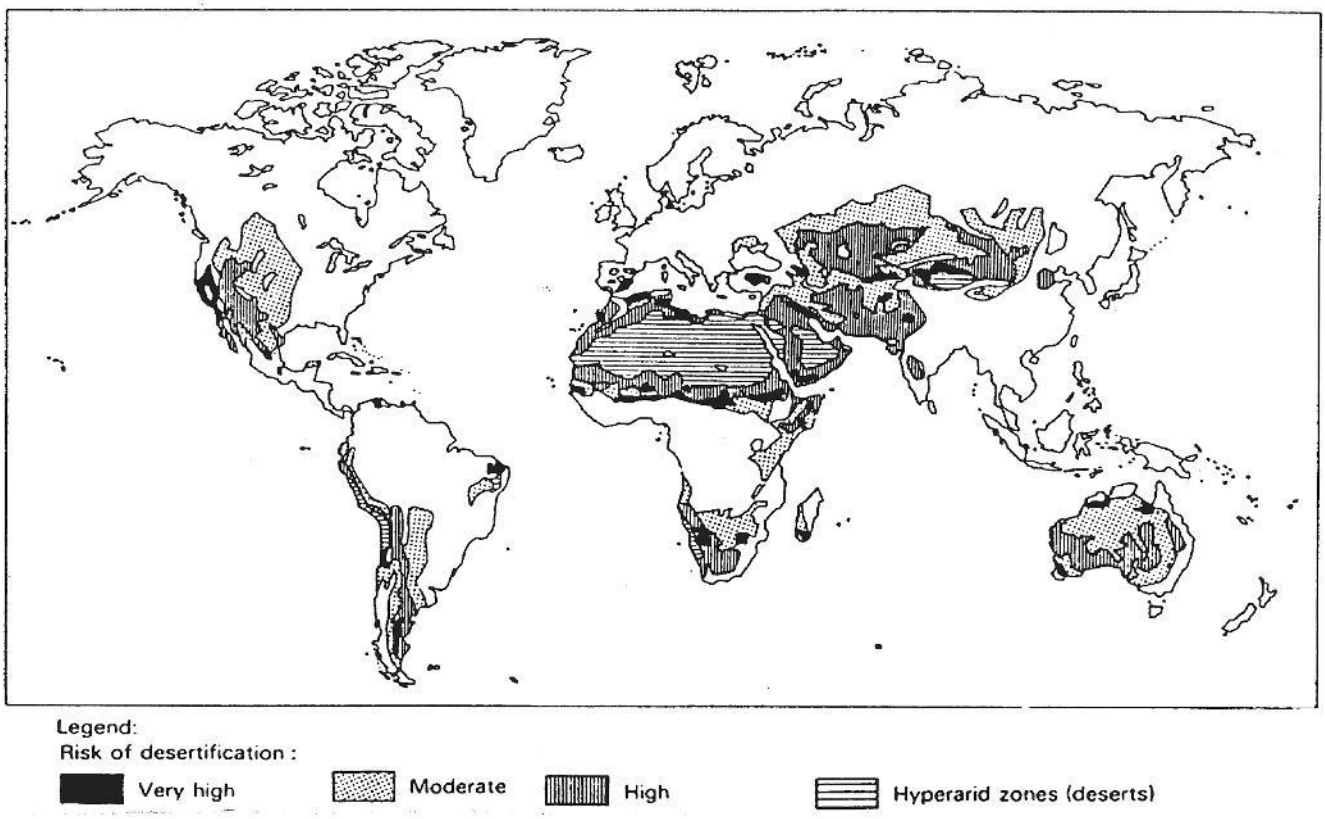
Desertification



About one billion people live in **arid** or semiarid **desert** lands that occupy about one third of the world's land surface. In these drier parts of the world, deserts are increasing rapidly from a combination of natural processes and human activities, a process known as desertification or land degradation. An annual rainfall of less than 10 in (25 cm) will produce a desert anywhere in the world. In the semiarid areas along the desert margins, where the annual rainfall is around 16 in (40 cm), the **ecosystem** is inherently fragile with seasonal rains supporting the temporary growth of plants. Recent changes in the **climate** of these regions have meant that the rains are now unreliable and the lands that were once semiarid are now becoming desert. The process of desertification is precipitated by prolonged droughts, causing the top layers of the **soil** to dry out and blow away. The eroded soils become unstable and compacted and do not readily allow for seeding. This means that desertified areas do not regenerate by themselves but remain bare and continue to erode. Desertification of grazing lands or croplands is accompanied, therefore, by a sharp drop in the productivity of the land.

Natural desertification is greatly accelerated by human activities that leave soils vulnerable to **erosion** by wind and water. The drier **grasslands** with too little rain to support cultivated crops have traditionally been used for grazing livestock. When semiarid land is overgrazed (by keeping too many animals on too little land), plants that could survive moderate grazing are uprooted and destroyed altogether. Since plant roots no longer bind the soil together, the exposed soil dries out and is blown away as dust. The destruction and removal of the **topsoil** means that soil productivity drops drastically. The obvious solution to desertification caused by **overgrazing** is to limit grazing to what the land can sustain, a concept that is easy to espouse but difficult to practice.

In the **Sahel** zone along the southern edge of the Sahara desert, settled agriculture and overgrazing livestock on the fragile scrublands have led to widespread soil erosion. Nomadic pastoralists, who have traditionally followed their herds and flocks in search of new pastures, are now prevented by national borders from reaching their chosen grazing grounds. Instead of migrating, the nomads have been encouraged to settle permanently and this has led to their herds overgrazing available pastures.

Other human factors leading to desertification include over-cultivation, **deforestation**, salting of the soil through **irrigation**, and the plowing of marginal land. These destructive practices are intensified in developing countries by rapid **population growth**, high population density, poverty, and poor land management. The consequences of desertification in some countries mean intensified **drought** and **famine** and lowered standards of living. It is estimated that desertification worldwide has claimed an area the size of Brazil (2 billion acres or 810 million ha) in the past 50 years. Each year new deserts consume an area the size of Belgium (15 million acres or 6 million ha), most of which is in the African Sahel.

In marginal areas throughout the world, traditional farming practices can lead to desertification. Plowing turns the top layer of the soil upside down, burying and killing weeds but exposing bare soil to erosion. In arid areas the

World deserts and areas at risk of desertification. (Beacon Press. Reproduced by permission.)

exposed soil dries out rapidly and is easily lost through wind erosion.

The processes of erosion and soil formation vary with climate and with the composition of the parent material. In balanced ecosystems, soil lost to erosion is replaced by new soil created by natural processes. On average, new soil is formed at a rate of about 5 tons an acre (12.5 tons per ha) per year, which is equivalent to a layer of soil about 0.2 in (0.4 cm) thick. This means that soils can sustain an erosion rate of up to 5 tons per acre per year and still remain in balance. However, much of the world's crop and forest land is not within this balance (with erosion running at two to 10 times the tolerable rate). In the United States about 6 tons of topsoil are lost for every ton of grains produced.

Forests are cut down for many different reasons. Some are cleared for agriculture, some for construction, some for paper products, and some to meet cooking and heating needs. Unfortunately, deforestation results in more than just the loss of trees, for soil is eroded, nutrients are lost to the ecosystem, and the water cycle is disrupted. The roots of the trees serve to bind the soil together and to hold water in the ecosystem, while the leaves of the trees break the force of the rain and allow it to soak into the topsoil. The result is that surface **runoff** from a forested hillside is half as much as from a grass-covered slope. Additionally, water soaking into the ground (rather than running off) leads to the natural recharge of **groundwater** and other **water resources**. Water and soil runoff from deforested hillsides cause **flooding** and **siltation** of agricultural and aquatic ecosystems in adjacent lowlands. Forests are also more efficient at reabsorbing and **recycling** the nutrients released from decaying **detritus** than are grasslands. Clearing forests therefore exposes the soil to both erosion and **nutrient** loss and alters the recharge of water reserves in the ecosystem.

Industrialized countries experienced a period of intense deforestation during the Industrial Revolution and even today much of the land has low productivity. Fortunately, most of these countries are now reforesting faster than they are deforesting. This is possible because their population growth is low, their agricultural production per acre is high, and their need for fuelwood for cooking and heating is optional, since **fossil fuels** and electricity are widely available. All of these factors release the pressure to further deforest the land.

In developing countries, on the other hand, high population growth rates and widespread poverty put pressure on the forests. Trees are needed for firewood, charcoal, and export, and the land is needed for farmland. In some developing countries deforestation exceeds replanting by five times. In Ethiopia, population and economic pressures pushed people to deforest and cultivate hillsides and marginally dry lands, and more than 1 billion tons of topsoil per year are now lost, resulting in recurrent famines. In parts of India and Africa there is so little wood available that dried animal dung is used to fuel cooking fires, an act that further robs the soil of potential nutrients. In Brazil, soil erosion and desertification have resulted from the conversion of forests to cattle ranches. In China, about one-third of its agricultural land has been lost to erosion, and the story is similar for many other countries.

The answer to erosion from deforestation is reforestation, better forest **conservation**, and better **forest management** to increase productivity. Planting trees on hillsides is particularly effective. Reforesting desertified areas first requires mulching the soil to hold moisture and the protection of the seedlings for several years until natural processes can regenerate the soil. Using these methods, Israel has achieved spectacular success in bringing desertlands (a product of past desertification) back to agriculture.

Desertification and its agents, deforestation and erosion, have been powerful shapers of human history. Agriculture had its roots in the once fertile crescent of the Middle East and in the Mediterranean lands. However, deforestation, overgrazing, and poor agricultural practices have turned once-productive pastureland and farmland into the near deserts of today. It is thought by some that deforestation and desertification may have even contributed to the collapse of the Greek and Roman Empires. Similar fates may have befallen the Harappan civilization in India's Indus Valley, the Mayan civilization in Central America, and the Anasazi civilization of Chaco Canyon, New Mexico, in what is today desertland.

Design for disassembly

For **recycling** to be broadly applicable, many environmentalists believe that products should be cheaper and easier to take apart so that they can be put together again and reused in other products.

Many large companies like Whirlpool, Digital Equipment, 3M, and General Electric have begun to design products in this regard. The BMW car, Z1, is considered to be the first to incorporate the concepts of disassembly. The plastic exterior of the car can be removed from the metal chassis in 20 minutes. The doors, bumpers, and front, rear, and side panels have been manufactured with recyclable plastic, and pop-in/pop-out fasteners replace screws and glues, whenever possible.

Composite materials, on the other hand, which are being used on a more widespread basis are difficult to recycle. Small juice boxes, for instance, which have become very popular are made of many layers of plastic, paper, and **aluminum**, which cannot be separated. *See also* Recyclables; Reuse; Waste management; Waste reduction

Detergents

A group of organic compounds that cause foaming and serve as cleansing agents based on their surface-active properties. A detergent molecule is termed surface-active because a portion of the molecule is hydrophilic and a portion is hydrophobic. It will therefore collect at the interface of water and another medium such as a gas bubble. Bubbles are stabilized by the surface-active molecules so that when the bubbles rise to the top of the bulk liquid, they maintain their integrity and form a foam. Surface-active agents can also agglomerate by virtue of their hydrophilic/hydrophobic **nature** to form *micelles* that can dissolve, trap, and/or envelop **soil** particles, oil, and grease. Surface-active agents are sometimes called *surfactants*. Synthetic detergents are sometimes referred to as *syndets*.

Detoxification

When many toxic substances are introduced into the **environment**, they do not remain in their original form, but are transformed to other products by a variety of biological and non-biological processes. The **chemicals** and their transformation products are degraded, converted progressively to smaller molecules, and eventually utilized in various natural cycles, such as the **carbon cycle**. Toxic metals are not degraded but are interconverted between available and non-available forms. Some organic compounds, such as polychlorinated biphenyl (PCBs), are degraded over a period of many

years to less toxic compounds, while compounds such as the **organophosphate** insecticides may break down in only a few hours.

The chemical transformations that occur may either increase (referred to as intoxication, or activation if the parent compound was nontoxic) or decrease (referred to as detoxification) the toxicity of the original compound. For example, elemental **mercury**, which has low toxicity, can be converted to methylmercury, a very hazardous chemical, through **methylation**. Parathion is a fairly nontoxic insecticide until it is converted in a living system or by photochemical reactions to paraoxon, an extremely toxic chemical. However, parathion can also be degraded to less toxic products by the process of hydrolysis.

In microbial degradation, the ultimate fate of the toxic chemicals may be mineralization (that is, the conversion of an organic compound to inorganic products), which results characteristically in detoxification; however, intermediates in the degradation sequence, which may be toxic or have unknown toxicity, may persist for a period of time, or even indefinitely. Likewise, since degradation pathways may contain many steps, detoxification may occur early in the degradation pathway, before mineralization has occurred. Detoxification may also be accomplished biologically through **cometabolism**, the **metabolism** by **microorganisms** of a compound that cannot be used as a **nutrient**; cometabolism does not result in mineralization, and organic transformation products remain. Studies have also shown that the structure and toxicity of many organic compounds can be altered by plants.

In modifying a toxic chemical, detoxifying processes destroy its actual or potential harmful influence on one or more susceptible animal, plant, or microbial **species**. Detoxification may be measured with the use of bioassays. A **bioassay** involves the determination of the relative toxicity of a substance by comparing its effect on a test organism with the conditions of a control. The scale or degree of response may include the rate of growth or decrease of a population, colony, or individual; a behavioral, physiological, or reproductive response; or a response measuring **mortality**. Bioassays can be used for environmental samples through time to determine detoxification of chemicals.

Both acute and chronic bioassays are used to assess detoxification. In an acute bioassay, a severe and rapid response to the toxic chemical is observed within a short period of time (for example, within four days for fish and other aquatic organisms and within 24 hours to two weeks for mammalian species). Detoxification of a chemical may be detected if there is a decrease in the observed toxicity of a test solution over the time of the acute test, indicating removal of the toxic chemical by degradation or other processes. Similarly, an increase in toxicity could indicate the formation of a more toxic transformation product.

Chronic bioassays are more likely to provide information on the rates of degradation, transformation, and detoxification of toxic compounds. Partial or complete life cycle bioassays may be used, with measurements of growth, reproduction, maturation, spawning, hatching, survival, behavior, and **bioaccumulation**.

Detoxification of chemicals should also be measured by toxicity testing that involves changes in different organisms and interactions among organisms, especially if the chemicals are persistent and stable and may accumulate and magnify in the **food chain/web**. Model ecosystems can be used to simulate processes and assess detoxification in a terrestrial-aquatic **ecosystem**. A typical ecosystem could include **soil** organisms, lake-bottom **fauna**, a plant, an insect, a snail, an alga, a crustacean, and a fish species maintained under controlled conditions for a period of time.

Most major types of reactions that result in transformation and detoxification of toxic chemicals can be accomplished either by biological (enzymatic) or by non-biological (nonenzymatic) mechanisms. Although significant changes in structure and properties of organic compounds may result from non-biological processes, the biological mechanism is the major and often the only mechanism by which organic compounds are converted to inorganic products. Microorganisms are capable of degrading and detoxifying a wide variety of organic compounds; presumably, every organic molecule can be destroyed by one or more types of microorganisms (referred to as the "principle of microbial infallibility.") However, since some organic compounds do accumulate in the environment, there must be factors such as unfavorable environmental conditions that prevent the complete degradation and detoxification of these persistent compounds. There are many examples where certain microorganisms have been identified as capable of detoxifying specific organic compounds. In some cases, these microorganisms can be isolated, cultured, and inoculated into contaminated environments in order to detoxify the compounds of concern.

The major types of transformation reactions include: oxidation, ring scission, photodecomposition, **combustion**, reduction, dehydrohalogenation, hydrolysis, hydration, conjugation, and chelation. Conjugation is the only reaction mediated by enzymes alone, while chelation is strictly nonenzymatic. Primary changes in organic compounds are usually accomplished by oxidative, hydrolytic, or reductive reactions.

Oxidation reactions are reactions in which energy is used in the incorporation of molecular oxygen into the toxic molecule. In most mammalian systems, a monooxygenase system is involved. One atom of molecular oxygen is added to the toxic chemical, which usually results in a decrease in

toxicity and an increase in water solubility, as well as provides a reaction group that can be used in further transformation processes such as conjugation. Microorganisms use a dioxygenase system, in which oxidation is accomplished by adding both atoms of molecular oxygen to the double bond present in various aromatic (containing benzene-like rings) **hydrocarbons**.

Ring scission, or opening, of aromatic ring compounds also can occur through oxidation. Though aromatic ring compounds are usually stable in the environment, some microorganisms are able to open aromatic rings by oxidation. After the aromatic rings are opened, the compounds may be further degraded by other organisms or processes. The number, type, and position of substituted molecules on the aromatic ring may protect the ring from enzymatic attack and may retard scission.

Photodecomposition can also result in the detoxification of toxic chemicals in the **atmosphere**, in water, and on the surface of solid materials such as plant leaves and soil particles. The reaction is usually enhanced in the presence of water; photodecomposition is also important in the detoxification of evaporated compounds. The **ultraviolet radiation** in sunlight is responsible for most photodecomposition processes. In photooxidation, for example, photons of light provide the necessary energy to mediate the reactions with oxygen to accomplish oxidation.

Combustion of toxic chemicals involves the oxidation of compounds accompanied by a release of energy. Often combustion does not completely result in the degradation of chemicals, and may result in the production of very toxic combustion products. However, if operating conditions are properly controlled, combustion can result in the detoxification of toxic chemicals.

Under **anaerobic** conditions, toxic compounds may be detoxified enzymatically by reduction. An example of a reductive detoxifying process is the removal of halogens from halogenated compounds. Dehydrohalogenation is another anaerobic process that also results in the removal of halogens from compounds.

Hydrolysis is an important detoxification mechanism in which water is added to the molecular structure of the compound. The reaction can occur either enzymatically or nonenzymatically. Hydration of toxic compounds occurs when water is added enzymatically to the molecular structure of the compound.

Conjugation reactions involve the combination of foreign toxic compounds with endogenous, or internal, compounds to form conjugates that are water soluble and can be eliminated from the biological organism. However, the toxic compound may still be available for uptake by other organisms in the environment. Endogenous compounds used in the conjugation process include sugars, amino **acid** residues, **phosphates**, and sulfur compounds.

Many metals can be detoxified by forming complexes with organic compounds by sharing electrons through the process of chelation. These complexes may be insoluble or nonavailable in the environment; thus the toxicant can not affect the organism. **Sorption** of toxic compounds to solids in the environment, such as soil particles, as well as incorporation into **humus**, may also result in detoxification of the compounds.

Generally, the complete detoxification of a toxic compound is dependent on a number of different chemical reactions, both biological and non-biological, proceeding simultaneously, and involving the original compound as well as the transformation products formed. *See also* Biogeochemical cycles; Biomagnification; Chemical bond; Environmental stress; Incineration; Oxidation reduction reaction; Persistent compound; Water hyacinth

Detritivores

Detritivores are organisms within an **ecosystem** that feed on dead and decaying plant and animal material and waste (called **detritus**); detritivores represent more than half of the living **biomass**. Protozoa, polychaetes, nematodes, Fiddler crabs, and filter-feeders are a few examples of detritivores that live in the salt marsh ecosystem. (Fiddler crabs, for instance, scoop up grains of sand and consume the small particles of decaying organic material between the grains.) While **microbes** would eventually decompose most material, detritivores speed up the process by comminuting, and partly digesting the dead, organic material. This allows the microbes to get at such material more readily. The continuing **decomposition** process is vital to the existence of an ecosystem—essential in the maintenance of **nutrient** cycles, as well as the natural renewal of **soil** fertility.

Detritus

Detritus is dead and decaying matter including the wastes of organisms. It is composed of organic material resulting from the fragmentation and **decomposition** of plants and animals after they die. Detritus is decomposed by bacterial activity, which can help cycle nutrients back into the food chain. In aquatic environments, detritus may make up a substantial percentage of the **particulate** organic **carbon** (POC) that is suspended in the water column. Animals that consume detritus are called "detritivores". Although detritus is available in large quantities in most ecosystems, it is usually not a very high quality food, and may be lacking in essential **nitrogen** or carbon compounds. **Detritivores** generally must expend a larger amount of energy to assimilate carbon and nutrients from detritus than from sources of food based on living plant or animal material. Some detritivores harbor beneficial bacteria or **fungi** in their guts to aid in the digestion of compounds that are difficult to degrade.

Dew point

An expression of humidity defined as the temperature to which air must be cooled to cause condensation of its water vapor content (dew formation) without the adding or subtracting of water vapor or changing its pressure. At this point the air is saturated and relative humidity becomes 100%. When the dew point temperature is below freezing it is also referred to as the frost point. The dewpoint is a conservative expression of humidity because it changes very little across a wide range of temperature and pressure, unlike relative humidity which changes with both. Dew points, however, are affected by water vapor content in the air. High dew points indicate large amounts of water vapor in the air and low dew points indicate small amounts. Scientists measure dew points in several ways: with a dew point hygrometer; from known temperature and relative humidity values; or from the difference between dry and wet bulb temperatures using tables. They use this measurement to predict fog, frost, dew, and overnight minimum temperature.

Diapers

see **Disposable diapers**

Diazinon

An **organophosphate pesticide**. Malathion and parathion are other well-known organophosphate pesticides. The organophosphates inhibit the action of the **enzyme** cholinesterase, a critical component of the chain by which messages are passed from one nerve cell to the next. They are highly effective against a wide range of pests. However, since they tend to affect the human nervous system in the same way they affect insects, they tend to be dangerous to humans, **wildlife**, and the **environment**. One of the most widely-used lawn **chemicals**, diazinon has been implicated in killing songbirds, pet dogs and cats, and causing near fatal poisonings in humans. The EPA banned its use on **golf courses** and sod farms after numerous reports of its killing ducks, geese, and other birds. *See also* Cholinesterase inhibitor

Dichlorodiphenyl-trichloroethane

Dichlorodiphenyl-trichloroethane (DDT) can be degraded to several stable breakdown products, such as DDE and DDD. Usually DDT refers to the sum of all the DDT-related components.

DDT was first developed for use as an insecticide in Switzerland in 1939, and it was first used on a large scale on the Allied troops in World War II. Commercial, non-military use began in the United States in 1945. The discovery of its insecticidal properties was considered to be one of the great moments in public health disease control, as it was found to be effective on the carriers of many leading causes of death throughout the world including **malaria**, dysentery, dengue fever, yellow fever, filariasis, encephalitis, typhus, **cholera**, and scabies. It could be sprayed to control mosquitoes and flies or applied directly in powder form to control lice and ticks. It was considered the "atomic bomb" of pesticides, as it benefited public health by direct control of more than 50 diseases and enhanced the world's food supply by agricultural **pest** control. It had eliminated mosquito transmission of malaria in the United States by 1953. In the first 10 years of its use, it was estimated to have saved five million lives and prevented 100 million illnesses worldwide.

Use of DDT declined in the mid-1960s due to increased **resistance** of different **species** of mosquitos and flies and other pests, and to increasing concerns regarding the potential harm to ecosystems and human health. Although the potential hazard from dermal **absorption** is small when the compound is in dry or powdered form, if the compound is in oil or an organic solvent it is readily absorbed through the skin and represents a considerable hazard.

Primarily DDT affects the central nervous system, causing dizziness, hyperexcitability, nausea, headaches, tremors, and seizures from acute exposure. Death can result from respiratory failure. It also is a liver toxin, activating microsomal **enzyme** systems and causing liver tumors. DDE is of similar toxicity. It became the focus of much public debate in the United States after the publication of *Silent Spring* by Rachel Carson, who effectively dramatized the harm to birds, **wildlife**, and possibly humans from the widespread use of DDT. Extensive spraying programs to eradicate Dutch elm disease and the **gypsy moth** (*Porthetria dispar*) also caused widespread songbird **mortality**. Its accumulation in the **food chain/web** also led to chronic exposures to certain wildlife populations. Fish-eating birds were subject to reproductive failure, due to egg shell thinning and sterility. DDT is resistant to breakdown and is transported long distances, making it ubiquitous in the world **environment** today. It was banned in the United States in 1972 after extensive government hearings, but is still in use in other parts of the world, mostly in developing countries, where it continues to be useful in the control of carrier-borne diseases. *See also* Acute effects; Chronic effects; Detoxification

Dieback

Dieback refers to a rapid decrease in numbers experienced by a population of organisms that has temporarily exceeded, or *overshot*, its **carrying capacity**. Organisms at low trophic levels such as rodents or deer, as well as weed **species** of plants, experience dieback most often. Without pressure from predators or other limiting factors, such "opportunistic" species reproduce rapidly, consume food sources to depletion, and then experience a population crash due chiefly to starvation (though reproductive failure can also play a part in dieback). The presence of predators—for instance, foxes in a meadow inhabited by small rodents—often results in a stabilizing effect on population numbers.

Die-off

Die-offs are the massive, sometimes unexplained but always unexpected, disappearances of plants and animals. The most well-known is probably the die-off of dinosaurs, but die-offs continue today in many regions of the world, including the United States.

Frogs and their kin are mysteriously vanishing in some areas, and scientists suspect that human alteration of ecosystems is partly responsible. On five continents, scientists in 19 countries have reported massive die-offs among amphibians. Frogs are good indicators of environmental change because of the permeability of their skin. They are extremely susceptible to toxic substances on land and in water. Decreasing rainfall in some areas may be a factor in the die-offs, as is **habitat** loss due to **wetlands drainage**. Other scientists are investigating whether increased **ultraviolet radiation** due to **ozone** depletion is killing toads in the Cascade Mountain Range.

Other multiple factors—such as **acid rain**, heavy metal and **pesticide** contamination of ponds and other surface water, and human predation in some areas—may be causing the amphibians to die off. In France, for example, thousands of tons of frog legs imported from Bangladesh and Indonesia are consumed each year.

Scientists also have recorded widespread declines in the numbers of migratory songbirds in the Western Hemisphere and of wild mushrooms in Europe. The decline in these so-called indicator organisms is a sign of declining health of the overall ecosystems.

The decline of songbirds is attributed to the loss or fragmentation of habitat, particularly forests, throughout the songbirds' range from Canada to Central America and northern South America. **Fungi** populations in Europe are dying off, and scientists think it is more than a problem of overharvesting. The health of forests in Europe is closely linked to the fungi populations, which point to the ecological decline of the forests. Some scientists believe that **air pollution** is also playing a role in their decline.

A massive die-off of millions of starfish in the White Sea has been attributed to radioactive military waste in the former Soviet Union. French scientists have recorded growing numbers of dead **dolphins** along the Riviera, probably due to **environmental stress** which left the animals too weak to fight off a **virus**.

Annie Dillard (1945 –)

American writer

Often compared to the American naturalist **Henry David Thoreau**, Dillard—a novelist, memoir writer, essayist, poet, and author of books about the natural world—is best known for her acute observation of the land, the seasons, the changing weather, and the **wildlife** within her intensely seen **environment**. Though born in Pittsburgh, Pennsylvania on April 30, 1945, Dillard's vision of nature's violence and beauty was most fully developed living in Virginia, where she received her B.A., 1967, and M.A., 1968, from Hollins College. She also lived in the Pacific Northwest from 1975–1979 as scholar-in-residence at the University of Western Washington, in Bellingham, and is adjunct professor of English and writer in residence at Wesleyan University, in Middletown, Connecticut, where she lives with her husband, Bob Richardson, and her daughter, Rosie. Since 1973, she has also been a columnist for *The Living Wilderness*, the magazine of the **Wilderness Society**, the leading organization advocating expansion of the nation's wilderness.

In 1975, Dillard won the Pulitzer Prize for general nonfiction for her first book of prose, *Pilgrim at Tinker Creek* (1974), subtitled "A mystical excursion into the natural world," in which she presented—quoting Henry David Thoreau—"a meteorological journal of the mind" based on her life in the Roanoke Valley, Virginia, where she had lived since 1965. Her vision of "power and beauty, grace tangled in a rapture of violence," of a world in which "carnivorous animals devour their prey alive," is also an intense celebration of the things seen as she wanders the Blue Ridge mountainside, the Roanoke creek banks, observing muskrat, deer, red-winged blackbirds, and the multitude of "free surprises" her environment unexpectedly, and fleetingly, displays. *Seeing* acquires a mystical primacy in Dillard's work.

The urgency of seeing is also conveyed in Dillard's only book of essays, *Teaching A Stone To Talk* (1982), in which she writes: "At a certain point you say to the woods, to the sea, to the mountains, the world, Now I am ready. Now I will stop and be wholly attentive." Dillard suggests that, for the natural phenomena that we do not use or eat, our only task is to witness. But in witnessing, she sees cruelty and suffering, making her question at a religious level what mystery lies at the heart of the created universe, of which she writes: "The world has signed a pact with the devil...The terms are clear: if you want to live, you have to die."

Unlike some natural historians or writers of environmental books, Dillard is not associated with a specific program for curbing the destructiveness of human civilization. Rather, what has been described as her loving attentiveness to the phenomenal world—"nature seen so clear and hard that the eyes tear," as one reviewer commented—allies her with the broader movement of writers whose works teach some other relationship to **nature** than exploitation. In *Holy the Firm* (1977), her 76-page journal of several days spent in Northern Puget Sound, Dillard records such events as the burning of a seven-year-old girl in a plane crash and a moth's immolation in a candle flame to rehearse her theme of life's harshness, but at the same time, to note, "A hundred times through the fields and along the deep roads I've cried Holy." In the end, Dillard is a sojourner, a pilgrim, wandering the world, ecstatically attentive to nature's bloodiness and its beauty.

The popularity of Dillard's writing during the late 1980s and 1990s can be judged by the frequency with which her work was reprinted during these decades. As well as excerpts included in multi-author collections, the four-volume *Annie Dillard Library* appeared in 1989, followed by *Three by Annie Dillard* (1990), and *The Annie Dillard Reader* (1994). During these years, she also served as the co-editor of two volumes of prose—*The Best American Essays* (1988), with Robert Atwan, and *Modern American Memoirs* (1995), with Cort Conley—and crafted *Mornings Like This: Found Poems* (1995), a collection of excerpts from other writers' prose, which she reformatted into verse.

Though a minor work, *Mornings Like This* could be said to encapsulate all of the qualities that have made Dillard's work consistently popular among readers: clever and playful, it displays her wide learning and eclectic tastes, her interest in the intersection of nature and science with history and art, and her desire to create beauty and unity out of the lost and neglected fragments of human experience.

Dioxin

Dioxin is the chemical byproduct of certain manufacturing processes or products. It develops during the manufacture of two herbicides known as **2,4,5-T** and **2,4-D**, which are the two components found in **Agent Orange**. Dioxin is also manufactured in several other chemical processes, including the chlorinated bleaching of pulp and paper. The issue of dioxin's toxicity is one of the most hotly debated in the scientific community, involving the federal government, industry, the press, and the general public.

While dioxin commonly refers to a particular compound known as tetrachlorodibenzo-p-dioxin, or TCDD, there are actually 75 different dioxins. TCDD has been studied in some manner since the 1940s, and the most recent information indicates that it is capable of interfering with a number of physiological systems. Its toxicity has been compared to **plutonium** and it has proven lethal to a variety of research animals, including guinea pigs, monkeys, rats, and rabbits.

TCDD is also the chemical that some scientists at the **Environmental Protection Agency** (EPA) and a broad spectrum of researchers have called the most carcinogenic ever studied. During the late 1980s and early 1990s, it was linked to an increased risk of rare forms of **cancer** in humans—especially soft tissue sarcoma and non-Hodgkins lymphoma—at very high doses. Some have called dioxin "the most toxic chemical known to man." According to **Barry Commoner**, Director of the Center for the Biology of Natural Systems at Washington University, the chemical is "so potent a killer that just three ounces of it placed in New York City's water supply could wipe out the populace."

Exposure can come from a number of sources. Dioxin can be air-borne and inhaled in drifting incinerator ash, aerial spraying, or the hand spray application of weed killers. Dioxin can be absorbed through the skin as people walk through a recently sprayed area such as a backyard or a golf course. Water **runoff** and **leaching** from agricultural lands treated with pesticides can pollute lakes, rivers, and underground aquifers. Thus, dioxin can be ingested in contaminated water, in fish, and in beef that has grazed on sprayed lands. Residues in plants consumed by animals and humans add to the contaminated **food chain/web**. Research has shown that nursing children now receive trace amounts of dioxin in their mother's milk.

Because it bioaccumulates in the **environment**, TCDD continues to be found in the **soil** and waterways in microscopic quantities over 25 years after its first application. Dioxin is part of a growing family of **chemicals** known as organochlorines—a class of chemicals in which **chlorine** is bonded with **carbon**. These chlorinated substances are created to make a number of products such as **polyvinyl chloride**, solvents, and refrigerants as well as pesticides. Hundreds or thousands of organochlorines are produced as by-products when chlorine is used in the bleaching of pulp and paper or the disinfection of **wastewater** and when chlorinated chemicals are manufactured or incinerated. The by-products of these processes are toxic, persistent, and hormonally active. TCDD is also part of current manufacturing processes, such as the manufacture of the wood preservative, **pentachlorophenol**.

If the exposure to dioxin is intense, there can be an immediate response. Tears and watery nasal **discharge** have been reported, as have intense weakness, giddiness, vomiting, diarrhea, headaches, burning of the skin, and rapid heartbeat. Usually, a weakness persists and a severe skin eruption known as chloracne develops after a period of time. The body excretes very little dioxin, and the chemical can accumulate in the body fat after exposure. Minute quantities may be found in the body years after modest exposure. Since TCDD's **half-life** has been estimated at as much as 10–12 years in the soil, it is possible that some TCDD—suggested to be as much as seven **parts per trillion** (ppt)—is harbored in the bodies of most Americans.

The development of medical problems may appear shortly after exposure, or they may appear 10, 12, or 20 years later. If the exposure is large, the symptoms develop more quickly, but there is a greater **latency** period for smaller exposures. This fact explains why humans exposed to TCDD may appear healthy for years before finally showing what many consider to be typical dioxin-exposure symptoms, such as cancer or immune system dysfunction. There is also a relationship between toxicology and individual susceptibility. Certain people are more susceptible to the effects of dioxin exposure than others. Once a person has become susceptible to the chemical, he or she tends to develop cross reactions to other materials that would not normally trigger any response.

Government publications and research funded by the chemical industry have questioned the relationship between dioxin exposure and many of these symptoms. But a growing number of private physicians treating people exposed to dioxins have become increasingly certain about patterns or clusters of symptoms. They have reported a higher incidence of cancer at sites of industrial accidents, including increases in rates of stomach cancer, lung cancer, soft-tissue sarcomas, and malignant lymphomas. Some reports have indicated that soft-tissue sarcomas in dioxin-exposed workers have

increased by a factor of 40, and there have also been indications of psychological and personality changes and an excess of coronary disease.

Many theories about the medical effects of dioxin exposure are based on the case histories of the thousands of American military personnel exposed to Agent Orange during the Vietnam War. Agent Orange, a chemical defoliant, was used despite the fact that certain chemical companies and select members of the military knew about its toxic properties. Thousands of American ground troops were directly sprayed with the chemical. Those in the spraying planes inhaled the chemical directly when some of the herbicides were blown back by the wind into the open doors of their planes. Others were exposed to accidental dumpings from the sky, when planes in trouble had to evacuate their loads during emergency procedures.

Despite what many consider to be the obvious dangers of dioxin, industries continue to produce residues and market products contaminated with the chemical. White bleached paper goods contain quantities of TCDD because no agency has required the paper industry to change its bleaching process. Women use dioxin-tainted, bleached tampons, and infants wear bleached, dioxin-tainted paper diapers. Some scientists have estimated that every person in the United States carries a body burden of dioxin that may already be unacceptable.

Many believe that the EPA has done less to regulate dioxin than it has done for almost any other **toxic substance**. Environmentalists and other activists have argued that any other chemical creating equivalent clusters of problems within specific groups of similarly exposed victims would be considered an epidemic. Industry experts have often downplayed the problems of dioxin. A spokesman for Dow Chemical has stated that "outside of chloracne, no medical evidence exists to link up dioxin exposure to any medical problems." The federal government and federal agencies have also been accused of protecting their own interests. During congressional hearings in 1989 and 1990, the Centers for Disease Control was found to falsify **epidemiology** studies on Vietnam veterans.

In April 1991, the EPA initiated a series of studies intended to revise their estimate of dioxin's toxicity. The agency believed there was new scientific evidence worth considering. Several industries, particularly the paper industry, had also pressured the agency to initiate the studies, in the hope that public fears about dioxin toxicity could be allayed. But the first draft of the revised studies, issued in the summer of 1992, indicated more rather than fewer problems with dioxin. It appears to be the most damaging to animals exposed while still in the uterus. It also seems to affect behavior and learning ability, which suggests that it may be a **neurotoxin**. These studies have also noted the possibility of extensive effects on the immune system.

Other studies have established that dioxin functions like a steroid hormone. Steroid hormones are powerful chemicals that enter cells, bind to a receptor or protein, form a complex that then attaches to the cell's chromosomes, turning on and off chemical switches that may then affect distant parts of the body. It is not unusual for very small amounts of a steroid hormone to have major effects on the body. Newer studies conducted on **wildlife** around the **Great Lakes** have shown that dioxin has the capacity to feminize male chicks and rats and masculinize female chicks and rats. In male animals, testicle size is reduced as is sperm count.

It is likely that dioxin will remain a subject of considerable controversy both in the public realm and in the scientific community for some time to come. However, even those scientists who question dioxin's long-term toxic effect on humans, agree that the chemical is highly toxic to experimental animals. Dioxin researcher Nancy I. Kerkvliet of Oregon State University in Corvallis characterizes the situation in these terms, "The fact that you can't clearly show the effects in humans in no way lessens the fact that dioxin is an extremely potent chemical in animals—potent in terms of immunotoxicity, potent in terms of promoting cancer." *See also* Bioaccumulation; Hazardous waste; Kepone; Organochloride; Pesticide residue; Pulp and paper mills; Seveso, Italy; Times Beach, Missouri

Discharge

A term generally used to describe the release of a gas, liquid, or solid to a treatment facility or the **environment**. For

example, **wastewater** may be discharged to a sewer or into a stream, and gas may be discharged into the **atmosphere**.

Disposable diapers

Disposable diapers were introduced by Procter & Gamble in 1961. First used as an occasional convenient substitute for cloth diapers, their popularity has since exploded. By 1990 they were the primary diapering method for 85% of American parents. As a result, 2.7 million tons of disposable diapers are discarded every year, a point decried by environmentalists.

Proponents of reusables argue that this accounts for only two to three% of America's **solid waste**. Although detailed studies have examined the influence of both kinds of diapers on such variables as water consumption, **water pollution**, energy consumption, **air pollution**, and waste generation, there are no indisputable conclusions about which choice is better for the **environment**. Each study was based on different assumptions and came to different conclusions. Most were commissioned by either the disposable-diaper or reusable-diaper industry, and each side put their respective diapers slightly ahead of the other's.

Disposable diapers and their packaging create more solid waste than reusables, and because they are used only once, consume more raw materials—petrochemicals and wood pulp—in their manufacture. And although disposable diapers should be emptied into the toilet before the diapers are thrown away, many people skip this step, which puts feces (that may be contaminated with pathogens) into landfills and incinerators. There is no indication, however, that this practice has resulted in any increase in health problems. But cloth diapers affect the environment as well. They are made of cotton, which is watered with **irrigation** systems and treated with synthetic fertilizers and pesticides. They are laundered and dried up to 78 (commercial) or 180 (home) times, consuming more water and energy than disposables. In fact, home laundering is less energy efficient than commercial because it is done on a smaller scale. Diaper services make deliveries in trucks, which expends another measure of energy and generates more **pollution**. Human waste from cotton diapers is treated in sewer systems. Some disposable diapers are advertised as **biodegradable** and claim to pose less of a solid-waste problem than regular disposables. Their waterproof cover contains a cornstarch derivative that decomposes into water and **carbon dioxide** when exposed to water and air. Unfortunately, modern landfills are airtight and little, if any, degradation occurs. Biodegradable diapers, therefore, are not significantly different from other disposables.

Dissolved oxygen

Dissolved oxygen (DO) refers to the amount of oxygen dissolved in water and is particularly important in **limnology** (aquatic **ecology**). Oxygen comprises approximately 21% of the total gas in the **atmosphere**; however, it is much less available in water. The amount of oxygen water can hold depends upon temperature (more oxygen can be dissolved in colder water), pressure (more oxygen can be dissolved in water at greater pressure), and **salinity** (more oxygen can be dissolved in water of lower salinity). Many lakes and ponds have anoxic (oxygen deficient) bottom layers in the summer because of **decomposition** processes depleting the oxygen. The amount of dissolved oxygen often determines the number and types of organisms living in that body of water. For example, fish like trout are sensitive to low DO levels (less than eight **parts per million**) and cannot survive in warm, slow-moving streams or rivers. Decay of organic material in water caused by either chemical processes or microbial action on untreated sewage or dead vegetation can severely reduce dissolved oxygen concentration. This is the most common cause of **fish kills**, especially in summer months when warm water holds less oxygen anyway.

Dissolved solids

Dissolved solids are minerals in solution, typically measured in **parts per million** (ppm) using an electrical conductance meter calibrated to oven-dried samples. In humid regions, dissolved solids are often the dominant form of **sediment** transport. Solution features such as caverns and **sinkholes** are common in limestone regions.

Water that contains excessive amounts of dissolved solids is unfit for drinking. Drinking water standards typi-

cally allow a maximum of 250 ppm, the threshold for tasting sodium chloride; by comparison, ocean water ranges from 33,000–37,000 ppm. **Phosphates** and **nitrates** in solution are the major cause of eutrophication (**nutrient** enrichment resulting in excessive growth of algae). Dissolved solids **buffer acid** precipitation; lakes with low levels are especially vulnerable. High levels occur in **runoff** from newly-disturbed landscapes, such as strip mines and road construction.

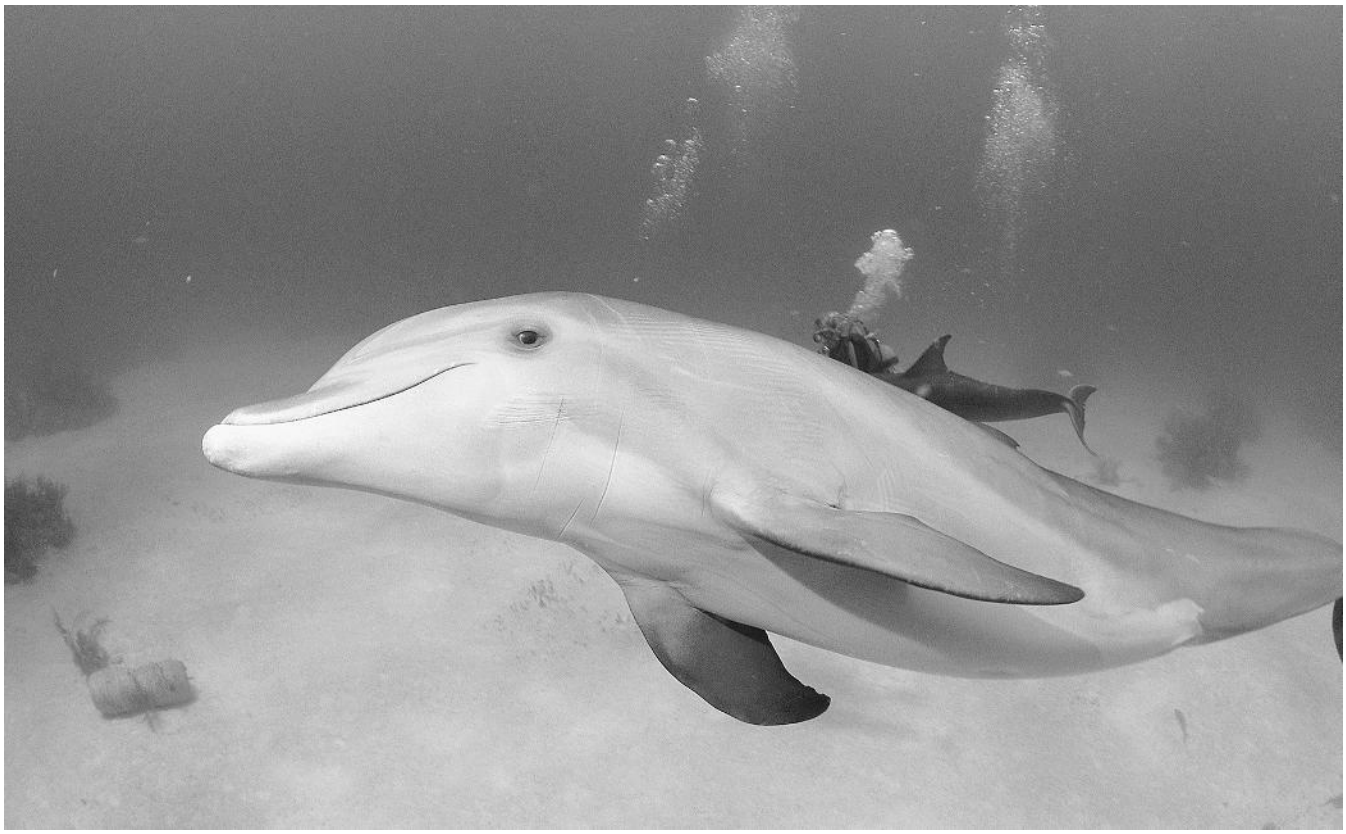
Dodo

One of the best known extinct **species**, the dodo (*Raphus cucullatus*), a flightless bird native to the Indian Ocean island of Mauritius, disappeared around 1680. A member of the dove or pigeon family, and about the size of a large turkey, the dodo was a grayish white bird with a huge black-and-red beak, short legs, and small wings. The dodo did not have natural enemies until humans discovered the island in the early sixteenth century.

The dodo became extinct due to **hunting** by European sailors who collected the birds for food and to predation of eggs and chicks by introduced dogs, cats, pigs, monkeys, and rats. The Portuguese are credited with discovering Mauritius, where they found a tropical paradise with a unique collection of strange and colorful birds unafraid of humans: **parrots and parakeets**, pink and blue pigeons, owls, swallows, thrushes, hawks, sparrows, crows, and dodos. Unwary of predators, the birds would walk right up to human visitors, making themselves easy prey for sailors hungry for food and sport.

The Dutch followed the Portuguese and made the island a Dutch possession in 1598 after which Mauritius became a regular stopover for ships traversing the Indian Ocean. The dodos were subjected to regular slaughter by sailors, but the species managed to breed and survive on the remote areas of the island.

When the island became a Dutch colony in 1644, the colonists engaged in a seemingly conscious attempt to eradicate the birds, despite the fact that they were not pests or obstructive to human living. But they were easy to kill. The few dodos in inaccessible areas that could not be found by the colonists were eliminated by the animals introduced by the settlers. By 1680, the last remnant survivors of the species were "as dead as a dodo."



The dodo from Mauritius became extinct during the seventeenth century. (Illustration by George Bernard, Science Photo Library. Photo Researchers Inc. Reproduced by permission.)

Interestingly, while the dodo tree (*Calvaria major*) was once common on Mauritius, the tree seemed to stop reproducing after the dodo disappeared, and the only remaining specimens are about 300 years old. Apparently, a symbiotic relationship existed between the birds and the plants. The fruit of this tree was an important food source for the dodo. When the bird ate the fruit, the hard casing of the seed was crushed, allowing it to germinate when expelled by the dodo.

Three other related species of giant, flightless doves were also wiped out on nearby islands. The white dodo (*Victoriornis imperialis*) inhabited Reunion, 100 mi (161 km) southwest of Mauritius, and seems to have survived up to around 1770. The Reunion solitaire (*Ornithoptera solitarius*) was favored by humans for eating and was hunted to **extinction** by about 1700. The "delightfully beautiful" Rodriguez solitaire (*Pezophaps solitarius*), found on the island of Rodriguez 300 mi (483 km) east of Mauritius, was also widely hunted for food and disappeared by about 1780.

Dolphins

There are 32 **species** of dolphins, members of the cetacean family Delphinidae, that are distributed in all of the oceans of the world. These marine mammals are usually found in relatively shallow waters of coastal zones, but some may be found in open ocean. Dolphins are a relatively modern group; they evolved about 10 million years ago during the late Miocene. The Delphinidae represents the most diverse group, as well as the most abundant, of all cetaceans. Among the delphinids are the bottlenose dolphins (*Tursiops truncatus*), best known for their performances in oceanaria; the spinner dolphin (*Stenella longirostris*), which have had their numbers decline due to tuna fishermen's nets; and the orca or the killer whale (*Orcinus orca*), the largest of the dolphins. Dolphins are distinguished from their close relatives, the porpoises, by the presence of a beak.

Dolphins are intelligent, social creatures, and social structure is variously exhibited in dolphins. Inshore species usually form small herds of two to 12 individuals. Dolphins of more open waters have herds comprised of up to 1,000 or more individuals. Dolphins communicate by means of echolocation, ranging from a series of clicks to ultrasonic sounds, which may also be used to stun its prey. By acting cooperatively, dolphins can locate and herd their food using this ability. Aggregations of dolphins also have a negative aspect, however. Mass strandings of dolphins, a behavior in which whole herds beach themselves and die *en mass*, is a well-known phenomenon but little understood by biologists. Theories for this seemingly suicidal behavior include nematode parasite infections of the inner ears, which upsets their balance, orientation, or echolocation abilities; simple disorientation due to unfamiliar waters; or even perhaps magnetic disturbances.

Because of their tendency to congregate in large herds, particularly in feeding areas, dolphins have become vulnerable to large nets of commercial fishermen. **Gill nets**, laid down to catch oceanic **salmon** and capelin, also catch numerous non-target species, including dolphins and inshore

species of porpoises. In the eastern Pacific Ocean, especially during the 1960s and 1970s, dolphins have been trapped and drowned in the purse seines of the tuna fishing fleets. This industry was responsible for the deaths of an average of 113,000 dolphins annually and in 1974 alone, killed over half a million dolphins in their nets. Tuna fishermen have recently adopted special nets and different fishing procedures to protect the dolphins. A panel of netting with a finer mesh, the Medina panel, is part of the net furthest from the fishing vessel. Inflatable power boats herd the tuna as the net is pulled under and around the school of fish. As the net is pulled toward the vessel many dolphins are able to escape by jumping over the floats of the Medina panel, but others are assisted by hand from the inflatable boats or by divers. The finer mesh prevents the dolphins from getting tangled in the net, unlike the large mesh which previously snared the dolphins as they sought escape. Consumer pressure and tuna boycotts were major factors behind this shift in techniques on the part of the tuna fishing industry. To advertise this new method of tuna fishing and to try to regain consumer confidence, the tuna fishing industry has begun labeling their products "dolphin safe." This campaign has been successful in that slumping sales from the boycotts have picked up over the last few years.

Dominance

Dominance is an ecological term that refers to the degree that a particular **species** is prevalent within its community, in terms of its relative size, productivity, or cover. Because of their ability to appropriate space, nutrients, and other resources, dominant species have a relatively strong or controlling influence on the structure and functions of their community, and on the fitness and productivity of other species. Ecological communities are often characterized on the basis of their dominant species.

Species may become dominant within their community if they are particularly competitive, that is, if they are relatively successful under conditions in which the availability of resources constrains **ecological productivity** and community structure. As such, competitive species are relatively efficient at obtaining resources. For example, competitive terrestrial plants are relatively efficient at accessing nutrients, moisture, and space, and they are capable of regenerating beneath their own shade. These highly competitive species can become naturally dominant within their communities.

Many ecological successions are characterized by relatively species-rich communities in the initial stages of recovery after disturbance, followed by the development of less-diverse communities as the most competitive species exert their dominance. In such cases, disturbance can be an important influence that prevents the most competitive species from dominating their community. Disturbance can play this role in two ways: (1) through relatively extensive, or stand-replacing disturbances that set larger areas back to earlier stages of **succession**, allowing species-rich communities to occupy the site for some time, or (2) by relatively local disturbances that create gaps within late-successional stands, allowing species-rich micro-successions to increase the amount of diversity within the larger community.

Some natural examples of species-poor, late-successional communities that are dominated by only a few species include the following: (1) the rocky intertidal of temperate oceans, where mussels (e.g., *Mytilus edulis*) may occupy virtually all available substrate and thereby exclude most other species, (2) eastern temperate forests of North America, where species such as sugar maple (*Acer saccharum*) and eastern hemlock (*Tsuga canadensis*) are capable of forming pure stands that exclude most other species of trees, and (3) a few types of tropical rain forests, such as some areas of Sumatra and Borneo where ironwood (*Eusideroxylon zwageri*) can dominate stands. In the absence of either stand-replacing disturbances or microdisturbances in these sorts of late-successional ecosystems, extensive areas would become covered by relatively simple communities dominated by these highly competitive species.

Humans often manage ecosystems to favor the dominance of one or several species that are economically favored because they are crops grown for food, fibre, or some other purpose. Some examples include: (1) cornfields, in which dominance by *Zea mays* is achieved by plowing, **herbicide** application, insecticide use, and other practices, in order to ensure that few plants other than maize are present, and that the crop species is not unduly threatened by pests or diseases; (2) forestry plantations, in which dominance by the crop species is ensured by planting, herbicide application, and other practices; and (3) grazing lands for domestic cattle, whose dominance may be ensured by fencing lands to prevent wild herbivores from utilizing the available forage, and by shooting native herbivores and predators of cattle. In all of the above cases, continued management of the **ecosystem** by humans is needed to maintain the dominance of the crop species. Otherwise, natural ecological forces would result in diminished dominance or even exclusion of the crop species.

Ecologists have developed a number of quantitative indices to describe the dominance of species within communities. One of these is known as the *community dominance index* (CDI). It is calculated as the percentage of the total abundance of all species in the community that is contributed by the two most abundant species, as in:

$$CDI = 100 \times (y_1 + y_2) / Y$$

where y_1 is the abundance of the most abundant species, y_2 is that of the second-most abundant species, and Y is the total of the abundances of all species in the community. For these purposes, abundance may be estimated by **biomass**, density, cover, productivity, or another suitable measurement. In general, communities with high values of CDI have relatively little community-level diversity. This relationship is being actively explored by ecologists who are interested in the environmental factors that control the levels of **biodiversity** in natural and managed ecosystems.

Dose response

Dose response is the relationship between the effect on living things and a stimulus from a physical, chemical, or biological source. Examples of stimuli include therapeutic drugs, pesticides, pathogens, and radiation. A quantal response occurs when the living thing either responds or does not respond to a stimulus of a given dose. Graded responses proportional to the size of the stimulus are also found in environmental applications. Some types of responses have a significant time effect. The Effective Dose for affecting 50% of a population of test subjects, ED_{50}, and the Lethal Dose for killing 50% of a population of test subjects, **LD_{50}**, are commonly used parameters for reporting the toxicity of an environmental pollutant. *See also* Pollution; Radiation exposure; Toxic substance

Double-crested cormorants

The double-crested cormorant (*Phalacrocorax auritus*) is a large (30–36 in; 73–90 cm), blackish water bird that eats fish and crustaceans. The double-crested cormorant population around the **Great Lakes** (but not in other areas) was once in serious decline. It has now has recovered. In fact, some fishermen feel that there are too many double-crested cormorants. These fishermen believe that an abundance of double-crested cormorants is responsible for a decline in fish populations in the Great Lakes. The **conservation** of this bird entails weighing the interests of the fishing industry against the interests of a now-abundant bird whose range is expanding.

The double-crested cormorant is a large migratory water bird native to North and Central America. The bird is found along the West Coast as far north as southern Alaska, wintering in Southern California and Baja California. On the East Coast it breeds from Maryland to Newfoundland, wintering along the southern coast to Florida, the Bahamas, and Cuba. Inland, double-crested cormorants breed along the upper Mississippi Valley and in the Great Lakes and winter on the Gulf Coast.

The first double-crested cormorant in the great Lakes region were sighted on the western shore of Lake Superior in 1913. By the 1940s, the population around the Great Lakes had increased to about 1,000 nesting pairs. Subsequently, the cormorant population began to decline. By 1973 a survey found only 100 pairs in the region.

In the early 1970s, cormorants were not the only water bird whose population was declining. Around this time, the United States Congress enacted several laws to protect cormorants and other waterfowl. For example, the **pesticide** DDT was banned in 1972. This chemical had entered lakes and rivers in run-off water and was implicated in reducing the birth rate of fish-eating birds, including the **bald eagle**. Congress also amended the Migratory Bird Treaty Act, first passed in 1917, to make it illegal to harm or kill cormorants and other migrating water fowl.

The double-crested cormorant populations around the Great Lakes began to increase in the 1980s, and the birds expanded their range eastward to **Lake Erie** and Lake Ontario. The return of the double-crested cormorant seemed to some conservationists to signal that the Great Lakes, once seriously polluted, were recovering. However, one reason the cormorant population may have increased around the Great Lakes is that **overfishing** during this time seriously depleted the number of large fish in the lakes. This led to an increase in the number of smaller fish such has smelt (*Osmerus mordax*) and alewife (*Alosa pseudoharengus*). Cormorants eat these small fish. An increase in their food supply may have contributed to an increase in the cormorant population.

Another ecological problem, the **zebra mussel**, may also have helped the cormorant. The zebra mussel is an exotic (non-native) invasive mussel that competes with native mussels for food resources. It is a voracious feeder and can clean lakes of green **plankton**, leaving the water particularly clear. Clear water may have helped the cormorant, which hunts fish by sight, find food more easily.

By the 1990s, some local cormorant populations had grown to unprecedented proportions, and at the same time, sport fish populations had declined. As a result, some Great Lakes fishermen, refusing to consider the role of overfishing in the decline of fish populations, blamed double-crested cormorants for steep drops in populations of fish such as smallmouth bass (*Micropterus dolomieui*), rock bass (*Ambloplites rupestris*), and brown bullheads (*Ameiurus nebulosus*). An adult cormorant weighs about four pounds, and eats about one pound of fish a day. Some areas hosted flocks of thousands of cormorants. A 1991 study of cormorants in Lake Ontario estimated that the birds had consumed about five million pounds of fish. In addition, cormorants tend to eat smaller fish, and if enough fish are eaten before they can reproduce, **future generations** of fish are threatened.

Although fishermen have blamed the cormorant for declining fish populations, conservationists have insisted on scientific studies to determine if these birds are indeed causing a decline in fish populations. A 1998 study of cormorants on Galloo Island in Lake Ontario found that the smallmouth bass, a popular sport fish, made up just 1.5% of the cormorant's diet. Yet because the cormorants ate small bass that had not yet grown to reproductive maturity, the bird was considered linked to the smallmouth's decline.

Another 2000 study of the Beaver Islands area in Lake Michigan concluded that it likely the large cormorant population was a factor in the declining numbers of smallmouth bass and other fish. Yet the biologist who led the study was unable to conclude that cormorants were entirely responsible for the decline in the fish population. However, **wildlife** officials took action to manage this cormorant population.

Cormorants also have made themselves unpopular because they nest in large colonies, where thick layers of their droppings can kill off underlying vegetation and leave the area denuded of all but a few trees. Cormorant colonies have endangered some sensitive woodland habitats and contributed to **soil erosion** by killing shoreline plants.

Because federal law protects double-crested cormorants, people cannot legally harass or kill these birds. In 1999, nine men were convicted of slaughtering 2,000 cormorants on Little Galloo Island in Lake Ontario. These men had illegally tried to reduce the cormorant colony by shooting adult birds. Soon after the incident, however, the New York Department of Environmental Conservation enacted a plan to reduce the Galloo colony from 7,500 to 1,500 birds over five years by spraying vegetable oil on cormorant eggs. The oil-coated eggs do not hatch. This method of thinning the flock was considered less disruptive to other wildlife and more humane than killing adult birds.

The New York program generated controversy, as not all scientists who had studied the birds believed that double-crested cormorants were responsible for the decline of the fish population, and some conservationists feared similar programs would be enacted against other fish-eating birds. Ironically, success in protecting the double-crested cormorant in the 1970s resulted in controversy two decades later. Even though the population of double-crested cormorants substantially increased, the bird is still under federal protection. Any action to manage the cormorant population must be carefully developed, implemented, and evaluated.

Marjory Stoneman Douglas (1890 – 1998)

American environmentalist and writer

A newspaper reporter, writer, and environmentalist renowned for her crusade to preserve Florida's **everglades**. Marjory Stoneman Douglas was part of the committee that first advocated formation of the Everglades **National Park** in 1927, and she has been an active advocate of the area's preservation ever since. Born In 1890 in Minneapolis and raised in Taunton, Massachusetts, Marjory Stoneman Douglas graduated from Wellesley College in 1912. After a brief marriage to Kenneth Douglas, a newspaper editor, she moved south to Florida in 1915 to join her father. She soon began to work as a reporter, columnist, and editor for the *Miami Herald*, founded by her father, Judge Frank Bryant Stoneman. During World War I, she left Miami to become the first female enlistee for the Naval Reserves, then joined the Red Cross, for which she worked and traveled in Europe during and after the war. Returning to Coconut Grove in 1920, Douglas remained there for over 75 years.

Douglas was involved very early in efforts to preserve the everglades from agricultural and residential development, as was her father before her. Her book, *The Everglades: River of Grass* was one of the most important statements publicizing the ecological importance and uniqueness of the

area, as well as its plight in the face of **drainage**, filling, and water diversion. Her framing of the region as a "river of grass" effectively instilled in the general public an idea of the interconnectedness of the land, water, plants, and animals of the area, helping to raise public awareness of the urgency of preserving the entire **ecosystem**, not just isolated components of it.

Douglas did not start out as a full-time environmental advocate. She wrote *The River of Grass* because she loved the history and the natural history of the area, and she was a long-time supporter of preserving the ecosystem, but she did not become deeply involved in the movement to save the everglades until the l970s. Friends of Douglas' in the **National Audubon Society**, confronted in 1969 by proposals to build an airport in the everglades, enlisted her aid and she helped organize the Friends of the Everglades, an organization that continues to defend the Park and related south Florida ecosystems.

Douglas proved to be an eloquent and forceful speaker and writer in the cause to save the everglades from development, and since the 1970s the everglades has become her single cause for celebrity. However she had also written poetry, short stories, histories, natural histories and novels, nearly all based in Florida. Initially her writing was popular at least in part because Florida and its history were little known, and rarely written about, when she began her literary career. Among her other publications are *Road to the Sun* (1951), *Hurricane* (1958), *Florida: the Long Frontier* (1967), and *Nine Florida Stories* (1990). She also wrote an autobiography, co-authored by J. Rothchild, *Marjory Stoneman Douglas: Voice of the River*.

In 1990, Douglas was honored on her one hundredth birthday with book signings, interviews, and banquets, and in 1992, she was back in action. That year, Douglas spoke out against President George Bush's proposal to modify the definition of "wetlands," a move that critics pointed out could open the door to future development. President Bill Clinton in 1993 called to wish her a happy birthday as she turned 103, and a few months later, awarded her the Presidential Medal of Freedom. In 1994, Florida state lawmakers passed the Everglades Forever Act, and also in the 1990s the federal government committed hundreds of millions of dollars to restore and protect the area. In 1996, Florida voters passed an amendment to their state's constitution that makes Everglades polluters, particularly sugar farmers, pay for clean-up costs, and more plans to save the **wetlands** were expected. However, voters did not pass a law to tax sugar at a penny a pound to assist with the effort; sugar producers had successfully argued that the ruling would cost many jobs.

Douglas received a bevy of honors in her lifetime, including Floridian of the Year in 1983 and a number of buildings, schools, and parks named after her. The building in Florida's capitol of Tallahassee that is home to the state Department of Natural Resources also bears her name, as does a special **conservation** award. Douglas died in her sleep at home on May 14, 1998.

On October 7, 2000, Douglas was inducted into the National Women's Hall of Fame in Seneca Falls, New York.

Drainage

The **hydrologic cycle** encompasses all movements of water molecules through the **atmosphere**, hydrosphere, and **groundwater** zones. One key part is the drainage of surface waters and groundwater back to the ocean. Natural drainage systems are well-adjusted to their **climate**, vegetation, and geology. Hydrologists and fluvial geomorphologists have studied these systems in great detail; human disturbances are readily apparent. Three impacts are considered here: wetland drainage and **irrigation**; dam construction and mining alterations; and urbanization.

Robert E. Horton identified many drainage characteristics during the 1930s and 1940s. Later researchers added other useful quantitative parameters. All of these show the predictable patterns found in natural drainage systems. Best known are stream order and drainage density. Although influenced by the detail of the maps used (commonly 1:24,000 or 1:62,500 topographic maps), stream order provides a simple system for ranking tributaries. The smallest ones are labeled first order, second-order streams have at least two first-order tributaries, third-order streams have at least two second-order tributaries, and so forth. The Mississippi River is ranked as a tenth- or twelfth-order stream, depending on the map scale used. Horton also developed a bifurcation ration between stream orders, which is generally around three; that is, on average there are three second-order streams for each third-order one.

Drainage density is a measure of channel length per unit area. This varies widely depending on the nature of the vegetation cover and **soil**. Badlands and deserts have high

drainage densities compared to well-vegetated basins with **permeable** soils.

Stream channels are finely adjusted to their drainage requirements, and attain a state of quasi-equilibrium. Human activities disrupt this equilibrium, forcing channel adjustments. This disruption is so pervasive that essentially all channels within settled areas have been impacted.

The earliest human intrusions are wetland drainage and irrigation of **arid** lands for agriculture. Recent litigation has involved decisions by federal officials to deny irrigation water to farmers in order to maintain needed supplies for endangered aquatic organisms. Only recently has the tendency to drain **wetlands** been reversed. With the comeback of the beaver from near **extinction**, wetland proponents now have an efficient ally.

Many large rivers have been dammed, with direct impact on the downstream riparian **environment**. To counteract this, in 1996, an experimental flood was produced on the **Colorado River** through the Grand Canyon, with the desired goal of improving **habitat** for **endangered species** there. Even farm ponds, through their sheer numbers, are major drainage interrupters. Another strong impact has come from mining, through the creation of huge holes, massive **sedimentation**, or increased **runoff**.

Urbanization has had the greatest local impact on drainage. Channels are altered, permeable areas are covered with impervious materials, and storm drains deliver runoff more rapidly to the overwhelmed drainage network. The effect is to deliver much more water in substantial less time, a sure formula for **flooding**.

Tulsa, Oklahoma, is a case study in urban flooding and costly **remediation**. A computerized system now evaluates rain and stream-gage data in real time, and issues flood warning via sirens throughout the city. Construction is banned within the 100-year flood, and valuable land has been set aside for detention ponds so that runoff does not exceed natural conditions up to the level of a 100-year flood. Though costly, these steps have been essential in order to protect lives and reduce property damage.

Changes in the drainage network are prime indicators of human impact. If we are to work with nature rather than fight her, we must understand and reckon with the impacts of our development on this fragile and finely tuned system.

Dredging

Dredging is a process to remove **sediment**. Dredging sediment to construct new ports and navigational waterways or maintain existing ones is essential for vessels to be able to enter shallow areas. Maintenance dredging is required because sediment suspended in the water eventually settles out, gradually accumulating on the bottom. If dredging were not done, harbors would eventually fill in and marine **transportation** would be severely limited. Dredging is also used to collect sediment (usually sand and gravel) for construction and other commercial uses. Hundreds of millions of cubic feet of sediment are dredged from marine bottoms annually in the United States and throughout the world.

One of the oldest types of dredging is agitation dredging, which uses a combination of mechanical and hydraulic processes and dates back over 2,000 years. An object is dragged along the bottom with the prevailing current; this suspends the sediment and the current carries the suspended material away from the area. Technology currently used to dredge sediment from a harbor, bay, or other marine bottom consists of hydraulic or mechanical devices. Hydraulic dredging involves suspending the sediment, which mixes with water to form a **slurry**, and pumping it to a **discharge** site. Mechanical dredging is typically used to dredge small amounts of material. It lifts sediment from the bottom by metal clamshells or buckets without adding significant amounts of water, and the dredged material is usually transferred to a barge for disposal at a particular site.

Most of the dredging that occurs in the United States is hydraulic dredging. Hopper dredges are vessels that employ hydraulic dredging, and they are often used in the open ocean or in areas where there is vessel traffic. The ship's hull is filled with dredged material and the ship moves the material to a designated disposal site where it is dumped through doors in the hull. Pipeline dredges use hydraulic dredging to remove sediment in nearshore areas, and the dredged material is discharged through a pipeline leading to a beach or diked area. Approximately 550 million wet metric tons of sediment are dredged from the waters of the United States each year, and an estimated one-third is disposed in the marine **environment**, accounting for the greatest amount of waste material dumped in the ocean. Of the dredged material dumped in the marine environment, 66% is disposed in estuaries. Two dozen marine disposal sites in the United States receive approximately 95% of all of the dredged material disposed at sea.

Dredged material is typically composed of **silt**, clay, and sand, and can sometimes include gravel, boulders, or-

ganic matter, as well as chemical compounds such as sulfides, hydrous oxides, and metal and organic contaminants. The grain size of the dredged sediment will determine the conditions under which the sediment will be deposited or resuspended if disposed in the marine environment.

The choice of where the dredged material should be placed depends on whether it is uncontaminated or contaminated by pollutants. If contaminated, the level of pollutants in the dredged material can also play a role in the decision of the type and location of disposal. Because many navigational channels and ports are located in industrialized areas, and because sediments are a sink for many pollutants, dredged material may be contaminated with toxic metals, organohalogens, **petrochemical** by-products, or other pollutants. Dredged material can also contain contaminants from agricultural and urban sources.

Dredged material with very little contaminants can be placed in a variety of locations and beneficially reused for beach restoration, construction aggregate, fill material, cover for sanitary landfills, and **soil** supplementation on agricultural land. The primary concerns over the disposal of uncontaminated dredged material in the marine environment are the physical impacts it can have, such as high turbidity in the water column, changes in grain size, and the smothering of bottom dwelling organisms. The ensuing alterations to the bottom **habitat** can lead to changes in the benthic community. Deposited dredged sediment is usually recolonized by different organisms than were present prior to the disposal of the dredged material. For example, disposal of sediment from a dredging project in Narragansett Bay, Rhode Island changed the bottom **topography** and sediment type, and this change in benthic habitat led to a subsequent decline in the clam and finfish fishery at the site and an increase in the lobster fishery. If the dredged material is similar to the sediment on which it is dumped, the area may be recolonized by the same **species** that were present prior to any dumping.

If dredged material is dumped in an area that has less than 197 ft (60 m) of water, most of the material will rapidly descend to the bottom as a high-density mass. A radial gradation of large-to-fine grained sediment usually occurs from the impact area of the deposition outward. Fine-grained material spreads outward from the disposal site, in some cases up to 328 ft (100 m), in the form of a fluid mud. It can range in thickness up to 3.9 in (1 dm). From one to five% of the sediment remains suspended in the water as a **plume**; this sediment plume is transient in **nature** and eventually dissipates by dispersion and gravitational settling. The long-term fate of dredged material dumped in the marine environment depends on the location of the dumping site, its physical characteristics such as bottom topography and currents, and the nature of the sediment. Deep-ocean dumping of dredged material results in wider dispersal of the sediment in the water column. The deposition of the dredged material becomes more widely distributed over the ocean bottom than in nearshore areas.

Dredging contaminated sediment poses a much more severe problem for disposal. Disposing contaminated dredged material in the marine environment can result in long-term degradation to the **ecosystem**. Sublethal effects, **biomagnification** of pollutants, and genetic disorders of organisms are some examples of possible long-term effects from toxic pollutants in contaminated dredged material entering the food chain. However, attributing effects from placement of contaminated dredged material at a marine site to a specific cause can be very difficult if other sources of contaminants are present.

Dredged material must be tested to determine contamination levels and the best method of disposal. These tests include bulk chemical analysis, the elutriate test, selective chemical **leaching**, and bioassays. Bulk chemical analysis involves measurements of volatile solids, **chemical oxygen demand**, oil and grease, **nitrogen**, **mercury**, lead, and zinc. But this chemical analysis does not necessarily provide an adequate assessment of the potential environmental impact on bottom dwelling organisms from disposal of the dredged material. The elutriate test is designed to measure the potential release of chemical contaminants from suspended sediment caused by dredging and disposal activities. However, the test does not take into account some chemical factors governing sediment-water interactions such as complexation, **sorption**, redox, and acid-base reactions.

Selective chemical leaching divides the total concentration of an element in a sediment into identified phases. This test is better than the bulk chemical analysis for providing information that will predict the impact of contaminants on the environment after the disposal of dredged material. **Bioassay** tests commonly use sensitive aquatic organisms to measure directly the effects of contaminants in dredged material as well as other waste materials. Different concentrations of wastes are measured by determining the waste dilution that results in 50% **mortality** of the test organisms. Permissible concentrations of contaminants can be identified using bioassay tests.

If dredged material is considered contaminated, special management and long-term maintenance are required to isolate it from the rest of the environment. Special management techniques can include capping dredged material disposed in water with an uncontaminated layer of sediment, a technique which is recommended in relatively quiescent, shallow water environments. Other management strategies to dispose contaminated dredged material include the use of upland containment areas and containment islands. The use of submarine burrow pits has also been examined as a possible means to contain contaminated dredged material.

There is more than one law in the United States governing dredging and disposal operations. The General Survey Act of 1824 delegates responsibility to the **Army Corps of Engineers** (ACOE) for the improvement and maintenance of harbors and navigation. The ACOE is required to issue permits for any work in navigable waters, according to the Rivers and Harbors Act of 1899. The Marine Protection, Research, and Sanctuaries Act (MPRSA) of 1972 requires the ACOE to evaluate the transportation and **ocean dumping** of dredged material based on criteria developed by the **Environmental Protection Agency** (EPA), and to issue permits for approved non-federal dredging projects. Designating ocean disposal sites for dredged material is the responsibility of EPA. The discharge of dredged material through a pipeline is controlled by the Federal **Water Pollution** Control Act, as amended by the **Clean Water Act** (1977). This act requires the ACOE to regulate ocean discharges of dredged material and evaluate projects based on criteria developed by the EPA in consultation with the ACOE. Other Federal agencies such as the U. S. **Fish and Wildlife Service** and the National Marine Fisheries Service can provide comments and recommendations on any project, but the EPA has the power to veto the use of proposed disposal sites. *See also* Agricultural pollution; Contaminated soil; Hazardous waste; LD50; Runoff; Sedimentation; Synergism; Toxic substance; Urban runoff

Drift nets

Drift nets are used in large-scale **commercial fishing** operations. Miles-long in length, nets are suspended from floats at various depths and set adrift in open oceans to capture fish or squid. Drift nets are constructed of a light, plastic monofilament that resists rotting. These nets are generally of a type known as gill nets, because fish usually become entangled in them by their bony gill plates. The fishing industry has found these nets to be cost-effective, but their use has become increasingly controversial. They pose a severe threat to many forms of marine life, and they have long been the object of protests and direct action from a range of environmental groups. National and international policies concerning their use have only recently begun to change.

Drift nets are not selective; there is no way to use them to target a particular species of fish. Drift nets can catch almost everything in their path, and there are few protections for species that were never intended to be caught. Although some nets can be quite efficient in capturing only certain species, the **bycatch** from drift nets can include not only non-commercial fish, but sea turtles, seabirds, seals and sea lions, **sharks**, porpoises, **dolphins**, and large whales. Nets that are set adrift from fishing vessels in the open ocean and never recovered pose an even more severe hazard to the marine environment. Lost nets can drift and kill animals for long periods of time, becoming what environmentalists have called "ghost nets."

Drift nets are favored by fishing industries in many countries because of their economic advantages. The equipment itself is relatively inexpensive; it is also less labor intensive than other alternatives, and it supplies larger yields because of its ability to capture fish over such broad areas. Drift-net fisheries can vary considerably, according to the target species and the type of fishing environment. In coastal areas, short nets can be set and recovered in an hour. The nets do not drift very far in this time and the environmental damage can be limited. But in the open ocean, where the target species may be widely dispersed, nets in excess of 31 mi (50 km) in length may be set and allowed to drift for 24 hours before they are recovered and stripped. The primary targets for drift netting include squid in the northern Pacific, salmon in the northeastern Pacific, tuna in the southern Pacific and eastern Atlantic, and swordfish in the Mediterranean.

Because of their cost-effectiveness, the Food and Agricultural Organization (FAO) of the United Nations actively promoted the use of drift nets during the early 1980s. **Earthwatch**, Earth Island Institute, and other environmental groups instituted drift-net monitoring during this period and founded public education programs to pressure drift-

Drift net. (Photograph by Dan Guravich. Photo Researchers Inc. Reproduced by permission.)

net fishing nations. The Sea Shepherd Conservation Society and other direct action groups have actually intervened with drift-net fishing operations on the high seas. Organizations such as these led international awareness about the dangers of drift nets, and their efforts have affected national and international policy. In December of 1991, the United Nations reversed its earlier endorsement of drift-net fishing and adopted General Assembly Regulations 44-225, 45-197, and 46-215 that totally banned high seas drift nets. The regulations applied to all international waters and went into effect on December 31, 1992. An agreement between the United States and the South and Central American countries of Costa Rica, Ecuador, Mexico, Nicaragua, Panama and Venezuela for a moratorium on drift nets was also signed. In 1998, the European Union banned all drift nets in its jurisdiction, with the exception of the Baltic Sea. The ban took effect in 2002. The regulatory body for the Baltic Sea is the International Baltic Sea Fishery Commission, which sets more liberal restrictions on nets and catch limits than the **European Union** (EU).

According to the United States National Marine Fisheries Service, enforcement of the drift net ban in the north Pacific has been successful, and the U.S. salmon fishery in these waters is no longer impacted by illegal drift nets. Enforcement of this ban in other waters has so far proven difficult, however, as drift net fishing is done in open oceans, far from national jurisdictions. In reaching enforceable international agreements about drift net fishing, the primary problem has been the large investment some nations have in this technology. Japan had 457 fishing vessels using drift nets in 1990, and Taiwan and Korea approximately 140 vessels each. France, Italy, and other nations own smaller fleets.

Japan and many of these nations are primarily concerned with protecting their investment, despite worldwide protest. The United States and Canada have both expressed concern about ecological integrity and the rate of unintended catch in drift nets, particularly the bycatch of North American salmon. In the 1990s, bilateral negotiations were pursued with Korea and Taiwan to control their drift net fleets. The International North Pacific Fisheries Commission has provided a forum for United States, Japan, and Canada to examine and discuss the economic advantages and environmental costs of drift net fishing. A special committee has

analyzed bycatch from drift nets used in the northern Pacific. Three avenues are currently being considered to control ecological damage: the use of subsurface nets, research into the construction of biodegradable nets, and alternative gear types for capturing the same species. The Irish Sea Fisheries Board has tested trawl nets as an alternative to drift nets, and found that they are effective in catching tuna. However, environmental groups have raised the concern that trawl nets also capture significant numbers of marine mammals, and have called for restrictions on their use after the Irish Sea Fisheries Board study found that more than 140 whales and dolphins were killed by trawlers during the two year study.

Drinking-water supply

The **Safe Drinking Water Act**, passed in 1974, required the **Environmental Protection Agency** (EPA) to develop guidelines for the treatment and monitoring of public water systems. In 1986, amendments to the act accelerated the regulation of contaminants, banning the future use of lead pipe, and requiring surface water from most sources to be filtered and disinfected. The amendments also have provisions for greater **groundwater** protection. Despite the improvement these regulations represent, only public and private systems that serve a minimum of 25 people at least 60 days a year are covered by them. Millions obtain their drinking water from privately owned **wells** that are not covered under the act.

Drinking water comes from two primary sources: surface water and groundwater. Surface water comes from a river or lake, and groundwater, which is pumped from underground sources, generally needs less treatment. Contaminants can originate either from the water source or from the treatment process.

The most common contaminants found in the public water supply are lead, nitrate, and radon–all of which pose substantial health threats. Studies indicate that substances such as **chlorine** and fluoride which are added to water during the treatment process may also have adverse effects on human health. Over 700 different contaminants have been found in water supplies in the United States, yet the EPA has only established maximum containment levels for 30 of them. Drinking water enforcement has been severely limited at both the state and federal levels. In 1990, 38,000 public water systems committed over 100,000 violations of the act, yet state governments only took legal enforcement action against 1,000, and the federal government took action against only 32. In only 6% of these cases were customers informed of the violations.

Chlorinated water was first used in 1908 as a means of reducing diseases in Chicago stockyards. **Chlorination**, which kills some disease-causing **microbes**, is now used to disinfect approximately 75% of the water supply in the United States. Numerous studies conducted over the past 20 years have found that chlorine reacts with organic products such as farm **runoff** or decaying leaves to form by-products that increase the risk of certain kinds of **cancer**. These by-products of chlorination are associated with cancer of the bladder and of the colon, probably because both store concentrated waste products. Research released by the Medical College of Wisconsin suggests that drinking chlorinated water increases the risk of bladder cancer by 20% and the risk of rectal cancer by 38%. Despite the correlation between chlorination by-products and these types of cancer, many still believe that the benefits of chlorine disinfection outweigh the risks. Some hope this study will prompt those in charge of public water systems to investigate other methods of disinfection, such as the use of **ozone** or exposure to ultraviolet light, both of which are currently used in Europe.

The effectiveness of fluoridated water in reducing dental cavities was first noted in communities with a naturally occurring source of fluoride in their drinking water, and controlled studies of communities where fluoride was added to the water confirmed the results. As of 1989, residents in 70% of all cities with populations greater than 100,000 were drinking fluoridated water. The EPA limit for fluoride in water is 4 **parts per million** (ppm), and most cities add only one ppm to their water. Fluoridated water also has adverse effects, and these may include immune system suppression, tooth discoloration, undesirable bone growth, **enzyme** inhibition, and carcinogenesis.

The EPA has set the acceptable level of lead in drinking water at 15 **parts per billion** (ppb), yet according to tests the agency has done, drinking water in almost 20% of cities in the United States exceeds that limit. The EPA has estimated that 25% of a child's lead intake comes from drinking water, and it cautions that the percentage could be much higher if the water contains high levels of lead. Depending on exposure, lead **poisoning** can cause permanent learning disabilities, behavioral and nervous system disorders, as well as severe brain damage and death. Service pipes made of lead and leaded solder used on **copper** plumb-

ing and brass faucets are the main sources of lead in water. Acidic or soft water increases the danger of lead contamination, because it corrodes the plumbing and leeches out the lead. About 80% of homes have water that is moderately to highly acidic. As of January 1, 1993, EPA regulations require all large public water companies to reduce the corrosiveness of water by adding calcium oxide or other hardening agents.

Chlorination and government standards for drinking **water quality** have virtually eliminated the outbreak of the classic water-borne diseases such as **cholera**, typhoid, and **malaria**. According to *The American Journal of Public Health*, however, recent studies have shown that water that meets current drinking water standards can still contain organisms which cause gastrointestinal (GI) disease. In a 15-month study conducted by the University of Quebec in Montreal, researchers equipped 299 homes with reverse-osmosis water **filters**, which remove bacterial and chemical contaminants. Over 600 families participated in the study, about half with the filters and half without them, and they were asked to keep records of all GI illnesses among household members. During this 15 month period, the households equipped with the water filters had 35% fewer incidents of GI illness and diarrhea. In 1992, *The New England Journal of Medicine* published a study showing that drinking water can harbor the bacterium that causes Legionnaire's disease. Some patients diagnosed with Legionnaire's disease were infected with the same type of *Legionella pneumophila* that was found in samples of their drinking water.

Vegetables, drinking water, and meat preservatives are the main sources of **nitrates and nitrites** in our diet. There is a definite link between nitrate and gastric cancer. Nitrate is converted to nitrite by bacteria in the mouth and stomach, and this is in turn converted into N-nitroso compounds, which have been proven highly carcinogenic in laboratory animals. Bottle-fed infants are at additional risk, because once the nitrate is converted to nitrite in the stomach it combines with fetal hemoglobin and converts to methaemoglobin. When 10% of the hemoglobin has been converted, cyanosis or **blue-baby syndrome** occurs; and when 70% of the hemoglobin is in methaemoglobin form, death occurs. According to a recent EPA report, half of the private wells in the United States contain nitrate.

Radioactivity occurs naturally and it can be present in drinking water. Preliminary studies have linked it to increased rates of **leukemia** and cancers of the bladder, breast, and lungs. The EPA has established 5 picocuries per liter (pCi/L) as the safe limit for radium in drinking water. An estimated 100–1,800 deaths per year are attributed to **radon** in tap water. According to EPA estimates over eight million people have excessively high radon levels in their water supply. Unlike most contaminants found in water, radon does not have to be ingested to pose a health hazard; dish washing, showering, or just running the faucet can agitate the water and release the radon into the air. According to EPA estimates, there are 10,000–40,000 lung-cancer deaths each year from radon inhalation. Radon is most frequently a problem in New England, North Carolina, and Arizona, and it is most likely to be found in well water and small water systems. Most large treatment facilities disperse radon during the treatment process.

Most water-treatment plants in the United States use chemical coagulation to remove impurities and contaminants. **Aluminum** sulfate is often added to the water, causing some contaminants to coagulate with the aluminum and precipitate out. The majority of the aluminum left in the water is removed by subsequent treatment processes, but a residual amount passes through the system to the consumer. Aluminum in drinking water has been linked with neurotoxicity, specifically Alzheimer's disease.

The organic **chemicals** that are found most frequently in drinking water are pesticides, trichloreothylene, and trihalomines. Pesticides usually make their way into drinking water through **seepage** and runoff in agricultural areas, and in high doses they can damage the liver, the kidney, and the nervous system, as well as increase the risk of various cancers. Trichloroethylene are industrial wastes and the populations at highest risk from this chemical have a water supply located near **hazardous waste** sites. The health risks associated with trichloroethylene are nervous system damage and cancer. Chlorination of water that is contaminated with organic matter is responsible for the formation of **trihalomethanes** in water, and preliminary studies suggest that it may increase cancer rates.

The bottled water industry is not sufficiently regulated, and it does not guarantee water purity. Despite the image portrayed by advertising, studies indicate that bottled water is not any safer in most cases than tap water. Home treatment units carry labels which frequently claim they are EPA-approved, but these are not regulated either. Different types of water filters are capable of removing different contaminants, so most experts recommend that anyone planning to install a treatment system have their water tested first.

Though scientific evidence clearly demonstrates that drinking water can be a health hazard, some of the most effective measures are also the easiest to implement. Studies have found that letting tap water run for several minutes reduces the lead content of the water by up to 70%. Companies that supply drinking water can be monitored by requesting copies of their test results and reporting any violations to the EPA. Lobbying for more stringent regulations is widely considered an effective tool for ensuring safe drinking water. Reduction of **pesticide** use and additional measures implemented for the protection of groundwater and surface water would also greatly reduce many of these health risks.

Drinking-water treatment

see **Water treatment**

Drip irrigation

Drip **irrigation** maximizes scarce resources by delivering water exactly where it is needed. The **percolation plume** from drip sources follows the bulb shape of the root zone, wasting little water. This also better controls **fertilizer** inputs by applying nutrients with the water application. Though expensive to install, and best-suited to perennials or high-value crops, this system overcomes or minimizes problems from traditional irrigation methods. Spray irrigation maximizes evaporation; while gravity-fed systems contribute to **seepage** losses, **waterlogging**, and **salinization**. Through water budget analyses and weed control, growers can maintain the exact moisture and nutritional levels needed for optimum plant growth.

Drought

Of all natural disasters, drought is the most subtle. Often, farmers cannot tell there is going to be a drought until it is too late. Unlike flash floods, drought is slow to develop. Unlike earthquakes, with destruction to the exterior **environment**, drought does its damage underground long before dust storms rage across the plains.

Technically, drought is measured by the decrease in the amount of **subsoil** moisture that causes crops to die or yield less (agricultural drought) or by a drop in the water level in surface reservoirs and below ground aquifers, causing **wells** to go dry (hydrological drought). Agricultural plus hydrological drought can lead to sociological drought. In this condition, drought effects food and water supplies to the extent that people have to rely on relief donations or are forced to migrate to another area.

Droughts are worldwide, repetitive, and unpredictable. Scientists believe there is a drought somewhere on the earth at any time. Nor are droughts recent developments; analysis of rock cores, glacial ice cores, and tree rings reveal prehistorical and historical droughts, some of which lasted for several decades. Tree rings in California, for example, record a 40-year-drought 300 years ago.

The direct cause of drought is a continued decrease in optimal rainfall. But what causes clouds not to form over an area, or the winds to carry rain-bearing clouds elsewhere, is complex. **Climate** change will alter the location of increased and reduced rainfall, so that some places that have always been well-watered will experience drought.

Some scientists believe that El Niño-La Niña events in the western Pacific Ocean are main drivers in the cause of droughts around the world. **El Niño**, an eastward flow of warm surface waters, creates a high pressure zone over the equator that results in a change in the high and low pressure zones in other parts of the world. This affects the flow of the jet stream and results in a disturbed rainfall pattern, causing, for example, excessive rain in California and drought in southwestern Africa, among other places. The **La Niña**, which usually follows El Niño, is an upwelling of cold deep waters in the western Pacific Ocean. It causes disturbed pressure zones that result in droughts in the Midwest, among other places.

Drought prediction is still in its infancy. Although scientists know that El Niño-La Niña events cause droughts in specific areas, they cannot yet predict when El Niño will occur. Weather satellites can measure subsoil moisture, a good indicator of incipient drought, but other factors also contribute to drought.

Lack of rain, for example, in the **Sahel**, is exacerbated by man-made environmental problems, such as cutting down trees for fuel and not allowing the **soil** to lie fallow, which conserves soil moisture. **Overgrazing** by animals such as cattle, goats, and sheep also contributes to the denuding of **topsoil**, which blows away in the wind, a condition known as **desertification**. Drought then becomes a cycle that feeds on itself: lack of trees reduces the amount of water vapor given off into the **atmosphere**; lack of topsoil reduces water retention. The result is that local rainfall is reduced, and the rain that does fall runs off and is not absorbed. Lack of rain has been the reason for five years of consecutive drought in Texas. The total amount of profit loss from 1998 until 2002 is estimated at $3.7 billion dollars.

Of all the water on the earth, less than 3% is fresh water. A lot of water is lost in evaporation, especially in **arid** climates, not only during rainfall but when it is stored in surface reservoirs. Rainwater or snowmelt that seeps into below-ground **permeable** rock channels, or aquifers, is pumped into wells in many communities. High-tech pumps have contributed to an increased drain on aquifers; if an **aquifer** is pumped too quickly, it collapses, and the ground above sinks. To increase water bank supplies, some communities recharge their aquifers by pumping water into them when they are low.

The only new water introduced into the **hydrologic cycle** is purified ocean water. **Desalinization** plants are expensive to build and maintain and often require burning **fossil fuels** or wood to run. Future plans include perfecting retrieving **solar energy** and **wind energy**.

Currently, farm **irrigation** uses most of the world's fresh water supply, but as city populations grow, they are expected to become the biggest consumers, and urban **conservation** measures will become imperative. Some communities already recycle **wastewater** for small farms and domestic garden use. Drought-causing industrial pollutants that "freeze" the water supply by rendering it toxic are being reduced and resolved under federal law. Reduced or low-flow shower heads and **toilets** are required in new construction in some states.

Distributing water from more to less abundant supplies by laying pipes and installing pumps within a state or a country requires money and management. If water is fed across state or international boundaries, legal and political negotiations are necessary.

During severe drought, sociologists find that people must either adapt, migrate, or die. Death, however, is usually caused by other factors such as war or poverty, as in the Sahel, where relief food supplies have been hijacked and sold at high prices, or where people in remote villages must walk to the distribution centers.

Some migrations have been permanent, as in the **migration** to California during the Midwestern **Dust Bowl** in the 1930s. Others are temporary, as in the Sahel region, where people migrate in search of food and water, crossing country lines.

Most people adapt in drought by making the most of their resources, such as building reservoirs or desalination plants or laying pipes connecting to more abundant water supplies. Farmers often invest in high-tech irrigation techniques or alter their crops to grow low-water plants, such as garbanzo beans.

Drought has also been the inspiration for inventions. The American West at the turn of the twentieth century gave rise to numerous rainmakers who used mysterious **chemicals** or noisemakers to attract rain. Most inventions failed or were unreliable, but out of the impetus to make rain grew silver iodide cloud-seeding, which now effects a 10–15% increase in local rainfall in some parts of the world.

Dry alkali injection

A method for removing **sulfur dioxide** from **combustion** stack gas. A **slurry** of finely ground alkaline material such as calcium carbonate is sprayed into the **effluent** gases before it enters the smokestack. The material reacts chemically with sulfur dioxide to produce a non-hazardous solid product, such as calcium sulfate, that can then be collected by **filters** or other mechanical means. The technique is called dry injection because the amount of water in the slurry is adjusted so that all moisture evaporates while the chemical reactions are taking place and a dry precipitate results. The use of dry alkali injection can result in a 90% reduction in the **emission** of sulfur dioxide from a stack. It is more expensive than wet alkali injection or simply adding crushed limestone to the fuel, but it is more effective than these techniques and results in a waste product that is relatively easy to dispose of. *See also* Air pollution control

Dry cask storage

Dry cask storage is a method of storing the **radioactive waste** from nuclear reactors. Dry cask storage refers to the containers that hold the waste and the system of storing the waste above ground in containers.

After World War II, nuclear **power plants** began generating electricity. By the close of the twentieth century, reactors at **nuclear power** plants generated 20% of the electricity in the United States. To produce electricity, **uranium** is used as fuel. Each tiny uranium pellet produces almost as much energy as a ton of **coal**. The pellets are contained in long metal rods, and these rods are placed in a fuel assembly that hold from 50 to 300 rods.

The uranium undergoes fission, a process that heats water and converts it to steam. The steam propels the blades of a turbine. This in turn spins the shaft of a generator where electricity is produced.

A large reactor uses 60 assemblies annually, and assemblies must be replaced after several years. The waste called spent fuel is so radioactive that a person standing near an

unshielded rod would die within a second. The spent fuel is also extremely hot. The used fuel rods are taken from the reactor core and stored in a concrete pool that is lined with steel. The rods are stored underneath at least 20 ft (6 m) of water. The spent pool set-up serves as a radiation shield while water cools the rods.

Spent fuel pools were regarded as temporary storage facilities. When operators built the first reactors, there were plans to extract and recycle unused uranium and **plutonium** from the fuel. However, the process would consolidate plutonium into a form that could be used in **nuclear weapons**. As a result of that consequence, the process was banned in 1977. By that time the United States had produced enough plutonium to satisfy its own needs for weapons production.

Five years later, Congress passed the Nuclear Waste Policy Act. Among the issues discussed was where to store spent fuel because power plants were starting reach to storage capacity. Congress amended the act in 1987 to designate a permanent waste disposal site in the **Yucca Mountain** area of Nevada.

Yucca Mountain had been proposed as a facility that would open in 1985. However, concerns about a nuclear explosion and other safety issues led to postponement of the opening. The opening was shifted to 1989, 1998, 2003, and 2010.

With no permanent site available, plant operators began to store spent fuel onsite in dry casks. In 1986, the United States **Nuclear Regulatory Commission** (NRC) licensed the first dry storage installation at the Virginia Electric & Power Company Surry Nuclear Plant in Jamestown, Virginia. The utility installed metal casks that were 16 ft (4.9 m) in height. Each dry cask held from 21 to 33 spent fuel assemblies. When filled, each cask weighed 120 tons. Casks were placed vertically on concrete pads that were 3-ft (1 m) thick. Each pad would hold 28 casks.

By 2001, the NRC had approved various dry casks designs. The container is usually steel. After it is filled, the container is either bolted or welded shut. The metal casks are then put inside larger concrete casks to ensure radiation shielding. Some systems involve placing the steel cask vertically in a concrete vault. In other systems, the container is placed horizontally in the concrete vault.

Discussions about dry cask safety in the twenty-first century have centered on the Yucca Mountain proposal. In May of 2002, the United States House of Representatives voted to approve the plan. That vote was an override of Nevada Governor Kenny Guinn's veto of the plan to send waste to Yucca. Opponents of the plan like the Nuclear Information and Resource Service maintained that casks of waste could not be transported safely by train or truck. In 2002, the facility was expected to cost $58 billion. It was scheduled to open in 2010 and hold a maximum of 77,000 tons of waste.

Dry cleaning

Dry cleaning is a process of cleaning clothes and fabrics with solutions that do not contain water. The practice has been traced back to France where around 1825 turpentine was used in the cleaning this process. According to Albert R. Martin and George P. Fulton in *Dry cleaning, Technology and Theory,* published in 1958, the tradition passed down regarding the origins of dry cleaning states that the process was discovered when "a can of 'camphene,' a fuel for oil lamps, was accidentally spilled on a gown and found to clean it, and this discovery led to the first dry cleaning establishment." Because of this, dry cleaning was referred to as "French cleaning" even into the second half of the twentieth century.

By the late 1800s, naphtha, **gasoline**, **benzene**, and benzol—the most common solvent—were being used for dry cleaning. Fire hazards associated with using gasoline for dry cleaning prompted the United States Department of Commerce in March 1928 to issue a standard for dry cleaning specifying that a dry cleaning solvent derived from **petroleum** must have a minimum flash point (the temperature at which it combusts) of 100°F (38°C). This was known as the Stoddard solvent.

The first chlorinated solvent used in dry cleaning was **carbon** tetrachloride. It continued to be used until the 1950s when its toxicity and corrosiveness were determined to be hazardous. By the 1930s, the use of trichloroethylene became common. In the 1990s the chemical was still being used in industrial cleaning plants and on a limited basis in Europe. This chemical's incompatibility with acetate dyes used in the United States brought about the end of its use in the United States. **Tetrachloroethylene** replaced other dry cleaning solvents almost completely by the 1940s and 1950s.

In 1990 about 53% of worldwide demand for tetrachloroethylene was for dry cleaning, and approximately 75% of all dry cleaners used it. However, in Japan petroleum-based solvents continued in use through the 1990s. By the late 1990s, perchloroethylene (perc or PCE) replaced tetrachloroethylene as the predominant cleaning solvent.

When the United States **Environmental Protection Agency** (EPA) issued national regulations to control air emissions of perc from dry cleaners in September 1993, environmental groups and consumers began to pay closer attention to the possible negative impact this chemical could have on human health. In July 2001, the American Council on Science and Health issued a report concluding that perc was not hazardous to humans at the levels most commonly used in dry cleaning. The report noted that, "Perchloroethylene has been the subject of close government and public scrutiny for more than 20 years. But government agencies in the United States and around the world have not agreed about the potential of environmental exposure to PCE to cause adverse health effects, including **cancer**, in humans."

The findings of this report included the following items:

- Inhalation of high levels of PCE and chemically similar solvents can cause neurological effects such as nausea, headache, and dizziness.
- High inhaled doses have been linked to changes in blood chemistry indicating that the liver and kidneys have been affected.
- These effects have been seen almost exclusively in workers, particularly in the dry-cleaning and chemical industries.
- There have been claims that reproductive difficulties are associated with occupational exposure to PCE.
- The claim that PCE is a **carcinogen** (cancer-causing substance) has received the most public and governmental attention. Concern has been expressed that environmental exposures to PCE in outdoor or indoor air and in drinking water can cause cancer in humans.
- Results of some epidemiological studies of dry cleaning and chemical workers exposed to PCE have been interpreted to suggest a relationship between occupational exposure and various types of cancer. Careful examination of the way in which these studies were conducted reveals serious problems including uncertainties about the amount of PCE to which people were exposed, failure to take into account exposure to other **chemicals** at the same time, and failure to take into account known confounders. Due to these deficiencies, these studies do not support a link between PCE and cancer or other adverse effects in humans.
- The differences between humans and rodents in the **metabolism** and mechanisms of action of PCE make it unlikely that the carcinogenic effects seen in mice and rats administered high levels of PCE will occur in humans exposed at environmentally relevant levels.
